The *TMC Textbook of Oncology* is dedicated to…

…. the countless patients who visit Tata Memorial Centre bestowing their faith upon this institution in their darkest hours. They are our *raison d'être!* We are grateful to them for their inspiration to work harder towards ever higher levels of clinical excellence...

… the trainee doctors, the heartbeat of our hospitals, whose hard work and commitment to service and education make TMC a great institution…

… the nursing staff whose unwavering commitment and profound dedication to patient care embody the heart and soul of our institution…

… to the paramedical staff of TMC, whose skills and dedication are indispensable to the care we provide…

… to colleagues from the departments of general and hospital administration, accounts, purchase, engineering, and all other supportive teams operating seamlessly in the background, who are the pillars that enable the smooth and efficient functioning of our institution…

… medical social workers who provide practical assistance, addressing vital aspects of patient care…

… to the workforce members of TMC, including housekeeping and other staff, whose work is often unseen, yet indispensable, and is the backbone of patient care...
… to the volunteers and Non-Governmental Organizations (NGOs) that collaborate with TMC and offer invaluable support to our patients…

Preface

It is with immense pride and a deep sense of responsibility that we present the *Tata Memorial Centre Textbook of Oncology.* This comprehensive volume, a collaborative effort led by faculty member colleagues of Tata Memorial Centre (TMC), along with contributions from TMC alumni, is more than just a textbook. It is a testament to the spirit of multidisciplinary oncology practice at TMC.

Our journey in creating the *Textbook of Oncology* was inspired by the diverse and complex landscape of cancer care in India. As a nation with vast demographic and geographic diversity, the challenges in cancer care are as unique as they are formidable. Recognizing this, our aim was to provide a resource that is not only academically rigorous but also deeply rooted in the practical realities of local practice. It offers an authentic overview of the TMC approach to multidisciplinary cancer care, with insights that, we hope, will be valuable both within and beyond India.

In presenting the *Textbook of Oncology*, our objective is twofold: to provide a comprehensive resource that contextualizes the practice of oncology in TMC and to offer insights into delivering high-quality cancer care in diverse global settings. Our focus has been on the practical application of oncological principles within Indian and similar healthcare systems. However, oncologists and healthcare professionals from developed countries will also find this resource enlightening, providing a broader perspective on how quality cancer care can be delivered in different parts of the world.

The *Textbook* is designed to cater to a wide array of readers—from undergraduate medical students to postgraduates specializing in general surgery, general medicine, paediatrics, gynaecology, radiation oncology, and other disciplines. A notable feature of the *Textbook* is its utility in preparing students for entrance and exit examinations. However, the content is not just theoretical; it is enriched with practical insights, thus preparing students for the practical aspects of cancer care. To the community of practising oncologists, it will serve as a reliable and up-to-date reference that encapsulates the essence of contemporary oncology practice.

As editors, two of us being surgical oncologists, one a medical oncologist, and another a radiation oncologist, we have witnessed firsthand the evolution of cancer diagnosis and treatment. Our collective experiences have taught us that cancer care is an ever-changing landscape requiring continuous learning and adaptation. The *Textbook*, therefore, not only covers the specifics of various cancers but also delves into broader themes such as cancer epidemiology, genetics, principles of systemic therapy, oncology-related training and education, and others. The chapters are structured to facilitate easy understanding and retention of complex concepts, making it an ideal study aid.

We extend our gratitude to all the authors who have contributed their knowledge and experience. Their dedication and expertise have been instrumental in shaping this work. We also wish to thank our publisher, Springer, for their collaboration and support in bringing this project to fruition. A special acknowledgement goes to the staff, particularly Mr Yogesh Kembhavi, the Editorial Assistant, whose diligent efforts and commitment have been crucial in the successful compilation and publication of the Textbook.

We are mindful of the profound influence that a great textbook can have on its readers. Throughout the history of medical education, certain texts have transcended their basic role as educational resources, becoming lifelong companions. Through this inaugural edition of the *TMC Textbook of Oncology*, we hope to sow the seeds of a work that will make its place as a trusted companion in the minds of its readers, to be consulted and cherished throughout their professional lives.

Mumbai,
Maharashtra, India

Acknowledgements

The editors wish to acknowledge the valuable contributions of several key departments and individuals whose efforts have been crucial in the realization of this project. We gratefully acknowledge the Department of Atomic Energy, Government of India, the parent Department of TMC, for its pivotal role in our journey, for believing in our capabilities, and for continuously inspiring us to strive for excellence. Tata Memorial Hospital Library for their indispensable support in research and access to critical resources, the Photography Department for their skilful work in creating high-quality images, the Institutional Review Boards (IRB), Ms. Diane Lamsback from Springer for her exceptional editorial assistance and guidance throughout the process of compiling and refining the *Textbook*, Dr Vijai Simha, Dr Pallavi Parab, Ms Prema Perumal, Mr Dinesh Jethwa, Mr Rohan Mane, Mr Vijendra Vanjare and Ms Sapna Koli for their important contributions during the editorial processes, and Mr Naren Aggarwal from Springer, who was instrumental in conceptualizing the Textbook with one of us.

Contents

Part I Basic Principles

Basic and Translational Science in Oncology 3
Dimple R. Bhatia and Sudeep Gupta

Surgical Oncology 17
Gouri Pantvaidya and Abhay Kattepur

Radiation Oncology 25
Siddhartha Laskar, Carlton Johnny, Jai Prakash Agarwal, and Shyam Kishore Shrivastava

Systemic Treatment of Cancer 37
Shona Nag and Sudeep Gupta

Pediatric Oncology 51
Badira Cheriyalinkal Parambil and Shripad D. Banavali

Oncopathology 61
Trupti Pai and Sangeeta Desai

Oncological Hematopathology 71
Nikhil Patkar, Shrinidhi Nathany, Pratyusha Gudapati, Arpan Mehta, Gaurav Chatterjee, Rohan Kodgule, Prashant Tembhare, P. G. Subramanian, and Sumeet Gujral

Microbiology in Oncology 89
Rohini Kelkar

Imaging in Oncology 99
Seema A. Kembhavi, Palak Bhavesh Thakkar (Popat), and Meenakshi H. Thakur

Nuclear Medicine in Oncology 113
Venkatesh Rangarajan, Nilendu C. Purandare, and Sandip Basu

Interventional Radiology in Oncology 133
Suyash S. Kulkarni, Nitin Sudhakar Shetty, Mohd Shariq, and Kunal Bharat Gala

Anaesthesia in Oncology 161
Vandana Agarwal, Aparna Chatterjee, Priya Ranganathan, and J. V. Divatia

Transfusion Medicine in Oncology 181
Priti Desai, Anisha Navkudkar, and Sunil Rajadhyaksha

Palliative Care in Oncology 189
Naveen Salins and Mary Ann Muckaden

Clinical Pharmacology in Oncology 199
Vikram Gota, Manjunath Nookala Krishnamurthy, Anand Patil, Jyoti Nehra, and Parsshava R. Mehta

Cancer Staging 213
Anuja Deshmukh, Harsh Dhar, Anand Ebin Thomas, and Anil K. D'Cruz

Part II Public Health

Cancer Registration in India 229
Rajesh Dikshit and Atul Budukh

Cancer Screening in India 239
Sharmila A. Pimple and Gauravi A. Mishra

Part III Hematological Malignancies

Adult Lymphoblastic Leukemias 253
Hasmukh Jain, P. G. Subramanian, Jayashree Thorat, Raajit Chanana, Swaratika Majumdar, Rushabh Kiran Kothari, and Rajesh Bollam

Adult Lymphomas 271
Manju Sengar and Sumeet Gujral

Adult Myeloproliferative Disorders/Myelodysplastic Syndromes/Overlap Syndromes 283
Sachin Punatar and Dhanlaxmi Shetty

Plasma Cell Dyscrasias 291
Prashant Tembhare, Goda Jayant Sastri, and Bhausaheb Bagal

Immunodeficiency-Associated Lymphoproliferative Disorders 307
Anant G. Gokarn and Tanuja Shet

Histiocytic and Dendritic Cell Neoplasms 319
Sridhar Epari and Gaurav Narula

Pediatric Acute Leukemias 331
Gaurav Narula, Nirmalya Roy Moulik, Chetan Dhamne, and Shripad D. Banavali

Pediatric Hodgkin Lymphoma 347
Gaurav Narula, Badira Cheriyalinkal Parambil, Chetan Dhamne, and Siddhartha Laskar

Pediatric Myeloproliferative Disorders/Myelodysplastic Syndromes/Overlap Syndromes 359
Vasudeva Bhat K and Hemani Jain

Hematopoietic Stem Cell Transplantation 367
Avinash Bonda and Navin Khattry

Part IV Solid Tumors

Central Nervous System (CNS) Tumors 379
Aliasgar Moiyadi, Vikas Singh, Raees Tonse, and Rakesh Jalali

Head and Neck Cancers 405
Prathamesh Pai, Sarbani Ghosh Laskar, and Avinash Pilar

Thyroid and Parathyroid Cancers. 437
Richa Vaish and Anil K. D'Cruz

Breast Cancer 451
Nita S. Nair, Tabassum Wadasadawala, Purvi Thakkar, Seema A. Kembhavi, Jyoti Bajpai, Seema Gulia, Rima Sanjay Pathak, Siddharth Turkar, and Rajendra A. Badwe

Non-Small Cell Lung Cancer 471
Naveen Mummudi, Anil Tibdewal, Kumar Prabhash, and Jai Prakash Agarwal

Small Cell Lung Cancer 487
Anil Tibdewal, Naveen Mummudi, Kumar Prabhash, and Jai Prakash Agarwal

Mediastinal Tumors 497
George Karimundackal, Virendra Kumar Tiwari, Apurva Ashok, Sabita Jiwnani, and C. S. Pramesh

Esophageal Cancer 507
Apurva Ashok, Sabita Jiwnani, George Karimundackal, and C. S. Pramesh

Biliary Tract Cancer 517
Bhawna Sirohi, Krunal Khobragade, Shraddha Patkar, Anant Ramaswamy, Monidipa Mondal, Supriya Chopra, Melroy Alistair D'Souza, and Mahesh Goel

Liver Cancer 535
Melroy Alistair D'Souza, Mahesh Goel, and Shraddha Patkar

Gastric Cancer 549
Manish S. Bhandare and Anant Ramaswamy

Colon Cancer 565
Ashwin deSouza, Shravan Nadkarni, Somnath Roy, Pritam Kataria, Anant Ramaswamy, and Vikas Ostwal

Small Intestine Cancer 593
Vikram A. Chaudhari, Parag R. Ingle, Manish S. Bhandare, and Shailesh V. Shrikhande

Anal Canal Cancer 599
Shirley Lewis, Reena Engineer, and Ashwin deSouza

Gastroenteropancreatic Neuroendocrine Tumors 611
Rajesh S. Shinde, Vikram A. Chaudhari, Manish S. Bhandare, and Shailesh V. Shrikhande

Rectal Cancer 625
Avanish Saklani, Ashish Pokharkar, Umasankar Tantravahi, Sanjeev Kumar, Pritam Kataria, Vikas Ostwal, Anant Ramaswamy, Supreeta Arya, and Shirley Lewis

Pancreatic Cancer 643
Shailesh V. Shrikhande, Vikram A. Chaudhari, Amit Narendra Chopde, and Manish S. Bhandare

Gastrointestinal Stromal Tumours 657
Anant Ramaswamy, Vikram A. Chaudhari, Sameer Shrirangwar, Pritam Kataria, Rushabh Kiran Kothari, Dharma Kumar K. G., and Vikas Ostwal

Renal Cancer 667
Ganesh Bakshi, Sameer Shrirangwar, Kunal Dholakia, Alok Goel, Shrikanth Atluri, Amandeep Singh Arora, and Amit Joshi

Adrenocortical Carcinoma 679
Amit Joshi, Kunal Dholakia, and Ganesh Bakshi

Urinary Bladder Cancer 687
Gagan Prakash, Amit M. Gupta, Sahil Sood, and Vedang Murthy

Upper Tract Urothelial Cancer 707
Kunal Dholakia, Rajesh Reddy, and Gagan Prakash

Prostate Cancer 717
Gagan Prakash, Hollis D’Souza, Abhay Kattepur, Abhilash Gavarraju, and Vanita Noronha

Penile Cancer 737
Ganesh Bakshi and Mahendra Pal

Testicular Cancer 751
Amit Joshi, Sameer Shrirangwar, Pritam Kataria, Alok Goel, and Nikhil Pande

Uterine Cancer 763
Lavanya Gurram, Shashank Srinivasan, Biswajit Dash, Palak Bhavesh Thakkar (Popat), and T. S. Shylasree

Cervical Cancer 777
Umesh Mahantshetty, Kedar Deodhar, Rahul D. Modi, and Rajendra Kerkar

Vulvar and Vaginal Cancers 795
T. S. Shylasree, Supriya Chopra, Richa Bansal, Arnab Bhattacharjee, and Jyoti Bajpai

Gestational Trophoblastic Disease 809
Seema Gulia, Vikas Talreja, Jaya Ghosh, Sudeep Gupta, and Jyoti Bajpai

Epithelial Ovarian Cancer 821
Jaya Ghosh, Amita Maheshwari, Bharat Rekhi, Palak Bhavesh Thakkar (Popat), Anuja Damani, Pabashi Poddar, and Umesh Mahantshetty

Non-Epithelial Ovarian Cancers 847
Jaya Ghosh, Amita Maheshwari, Bharat Rekhi, Palak Bhavesh Thakkar (Popat), Sushmita Rath, and Ram Abhinav Kannan

Bone Sarcomas 857
Jyoti Bajpai, Prakash Nayak, and Ajay Puri

Soft-Tissue Sarcoma 873
Srinath Gupta, Nehal R. Khanna, Ashish Gulia, and Siddhartha Laskar

Ewings Sarcoma 885
Tushar Vora and Siddhartha Laskar

Wilms Tumor 895
Badira Cheriyalinkal Parambil and Girish Chinnaswamy

Neuroblastoma 907
Sajid S. Qureshi, Monica Bhagat, and Tushar Vora

Retinoblastoma 921
Kalasekhar Vijayasekharan and Girish Chinnaswamy

Rare Pediatric Tumors 935
Subramaniam Ramanathan, Nirmalya Deo Pradhan, and Girish Chinnaswamy

Childhood and Adolescent Extracranial Germ Cell Tumors 945
Subramaniam Ramanathan and Maya Prasad

Hepatoblastoma 957
Maya Prasad

Part V Special Topics in Oncology

Emergencies 969
Vikas Talreja, Vijay Patil, Rahul Krishnatry, and Seema Gulia

Pain Management 983
Raghu S. Thota and Parmanand Jain

Intensive Care 995
J. V. Divatia, Jacob George Pulinilkunnathil, and Sheila Nainan Myatra

Vascular Access 1009
Sajid S. Qureshi and Nizamudheen M. Pareekutty

Comorbidities in the Cancer Patient 1019
Aruna Alahari Dhir, Sandeep P. Tandon, Sheela Prashant Sawant,
Maheema A. Bhaskar, Anuprita Dilip Daddi, and Aparna Iyer

Hereditary Cancers 1031
Rajiv Sarin

Library and Information 1047
Medha Joshi

Oncology Training and Education in India 1057
Siddhartha Laskar, Anant Ramaswamy, Garvit Chitkara, and Shripad D. Banavali

Editors and Contributors

About the Editors

Rajendra A. Badwe, MBBS, MS completed his MBBS from the King Edward Memorial Hospital, Mumbai, in 1978 followed by an MS in General Surgery from the same institution. Subsequently he trained at Tata Memorial Hospital, Mumbai, Toronomon Hospital, Tokyo, and the Royal Marsden Hospital, London. He joined Tata Memorial Centre in the Department of Surgical Oncology (Breast Cancer Unit) as a faculty member in 1992 and was the Director of TMC from 2008 to 2023. Currently he is the Emeritus Professor of Surgical Oncology, TMC. He is an internationally renowned breast cancer surgeon and researcher with seminal contributions in several themes including use of perioperative interventions to improve long-term outcomes. He has received numerous national and international awards, including the Padma Shri by the Government of India in 2013.

Sudeep Gupta, MBBS, MD, DM completed his MBBS, MD, and DM (Medical Oncology) from the All India Institute of Medical Sciences, New Delhi, in 2000 and has been a faculty member in the Department of Medical Oncology, Tata Memorial Centre, since 2001 and the Director of Advanced Centre for Treatment, Research and Education in Cancer (ACTREC), Navi Mumbai, from 2018 to 2023. Currently he is the Director of Tata Memorial Centre. His areas of expertise include breast cancer, gynecological cancers, clinical trial design, investigator-driven and industry sponsored clinical trials, tumor evolution, and endocrine treatment resistance in breast cancer. He led the landmark study which established the superiority of concurrent chemoradiation over neoadjuvant chemotherapy-surgery in locally advanced cervical cancer.

Shailesh V. Shrikhande, MBBS, MS, MD, FRCS (Hon), FASA (Hon) completed his MBBS (1992) and MS (General Surgery, 1997) from Lokmanya Tilak Municipal Medical College, Mumbai. He joined Tata Memorial Centre as a faculty member in 2002 and is currently the Deputy Director of Tata Memorial Hospital and Head of Gastrointestinal and Hepato-Pancreatic-Biliary Surgical Unit. He is an internationally acclaimed pancreatic cancer surgeon and has performed over 1200 Whipple operations. He is a renowned teacher, has conducted 60 masterclass teaching demonstrations of gastrointestinal surgeries, been a visiting Professor to 8 institutions in Europe, Japan, and USA, edited 9 oncology textbooks, authored 77 book chapters, and published over 300 scientific papers. He is the President of the Asia Pacific HPB Association and Secretary General-Elect of the International Hepato-Pancreato-Biliary Association (IHPBA). He has received numerous accolades and awards including the prestigious Honorary Fellowship of the American Surgical Association.

Siddhartha Laskar, MBBS, MD, DNB completed his MBBS from Guwahati Medical College and MD (Radiation Oncology) from Tata Memorial Hospital, Mumbai, in 1996, and has been a faculty member in the Department of Radiation Oncology, Tata Memorial Centre, since 2000. He specializes in the treatment of pediatric, bone and soft tissue, and hematolymphoid malignancies, with special expertise in interstitial brachytherapy and proton therapy. He has been an executive committee member of the International Society of Pediatric Radiation Oncology and chairman of the Sarcoma Group of the Indian Pediatric Oncology Group (InPOG). He serves as an expert faculty for the International Atomic Energy Agency (IAEA) and the European Society for Therapeutic Radiotherapy/Oncology (ESTRO) and is also a steering committee member of the International Lymphoma Radiation Oncology Group (ILROG). Dr. Laskar is a recipient of the prestigious Nollenberg Prize for research in bone sarcomas and has more than 150 publications in peer-reviewed national and international journals and books.

Part I

Basic Principles

Basic and Translational Science in Oncology

Dimple R. Bhatia and Sudeep Gupta

Abbreviations

APC/C	Anaphase-promoting complex/cyclosome
APE	Apurinic/apyrimidinic (AP) endonuclease
APML	Acute promyelocytic leukemia
ATM	Ataxia-telangiectasia mutated kinase
ATRA	All-*trans* retinoic acid
BER	Base excision repair
CAR	Chimeric antigen receptor
CCNE1	Cyclin E1
CCNE2	Cyclin E2
CDKi	Cyclin-dependent kinase (CDK) inhibitor
CENP-C	Centromere protein C
CHK1	Checkpoint kinase 1
CML	Chronic myelogenous leukemia
DBD	DNA-binding domain
DDR	DNA damage repair
DNA-PK	DNA-dependent protein kinase
DNMT	DNA methyltransferase
DSBs	Double-strand breaks
E2F-DP	E2 promoter binding factor-dimerization partner
ECs	Endothelial cells
EGF	Epidermal growth factor
FAK	Focal adhesion kinase
HDAC	Histone deacetylase
HGF	Hepatocyte growth factor
HIC-1	Hypermethylated in cancer
HR	Homologous recombination
ICAM1	Intercellular adhesion molecule 1
JAK	Janus-activated kinase
KAI-1	Kangai-1
LOH	Loss of heterozygosity
MMP	Matrix metalloproteinase
MQ	Methylene quinuclidinone
NER	Nucleotide excision repair
NHEJ	Non-homologous end joining
PARP	Poly (ADP-ribose) polymerase
PCNA	Proliferating cell nuclear antigen
PHTS	Phosphatase and tensin homologue deleted on chromosome 10 (PTEN) hamartoma tumor syndrome
PLK1	Polo-like kinase 1
polβ	Polymerase-β
PPARγ	Peroxisome proliferator-activated receptor-gamma
PTEN	Phosphatase and tensin homologue deleted on chromosome 10 (PTEN)
RANKL	Receptor activator of nuclear factor kappa B (NF-κB) ligand
Rb	Retinoblastoma
ROS	Reactive oxygen species
RTK	Receptor tyrosine kinase
SAC	Spindle assembly checkpoint
SDF1	Stromal cell-derived factor 1
SSB	Single-strand break
STK	Serine/threonine kinase
TAM	Tumor-associated macrophage
TCR	T-cell receptor
TGF-β	Transforming growth factor-β
TME	Tumor microenvironment
VCAM1	Vascular cell adhesion molecule 1
WT	Wild-type

1 Introduction

Cancer ranks amongst the top five leading causes of death worldwide. According to recently published data, an estimated 18.1 million new cancer cases and 9.6 million cancer deaths had occurred in 2018 [1]. Although the incidence of

cancers is lower in developing regions of the world, they account for a majority of the cancer burden because of their population size. In India, there were an estimated 1.15 million new cases and 0.78 million deaths in 2018 [1]. Furthermore, the burden of cases and deaths is expected to increase in the coming decades because of a variety of reasons, most important among which is the likely aging of the world's population. This picture positions translational cancer research as one of the top health research priorities worldwide. A comprehensive understanding of the tumor biology and the pathophysiological processes that govern cancer onset and spread is required for the development of detection techniques, diagnostic and prognostic biomarkers, novel therapies, and cancer prevention strategies. Innovative research to address these key areas of development is helped by continuous mining and analysis of the so-called "omics" data obtained through advancements in technology. In this chapter, we describe the outcome of research in some of the most important themes in cancer, namely, tumor cell biology, hallmarks of cancer, DNA repair mechanisms, regulation of gene expression, functions of oncogenes and tumor suppressors, and the role of the immune system in regulation of cancer initiation and spread.

2 Hallmarks of Cancer

"Hallmarks of cancer" is a term coined by Hanahan and Weinberg to summarize the principal characteristics of malignant cells and their possible underlying molecular underpinnings, which they reported in two famous papers [2, 3]. The "hallmarks of cancer" framework provides a set of 10 major principles that encompass the complexity of cancer biology. By definition, these hallmarks are "distinctive and complementary capabilities" that enable tumor growth and metastatic dissemination [2, 3]. A summary of these hallmarks is listed in Table 1. Of these, the six acquired capabilities—self-sufficiency in growth signals, insensitivity to anti-growth signals, evading apoptosis, limitless replicative

Table 1 Cancer hallmarks [2, 3]

Hallmark	Pathogenicity	Mechanism	Therapeutic targeting of hallmarks (examples)
Acquired capability: self-sufficiency in growth signals	Uncontrolled growth and cell division	Oncogene addiction/signaling, signaling between different cell types in the heterogeneous tumor	EGFR inhibitors
Acquired capability: insensitivity to anti-growth signals	Unchecked proliferation	Switch off of the cell cycle checkpoints, avoiding cytostatic anti-growth signals	CDKis
Acquired capability: evading apoptosis	Evading cell attrition	Inactivation of tumor suppressors like pRb, p53, etc.	Inhibitors to rescue mutant p53 conformation and function to restore wild-type p53 activity
Acquired capability: limitless replicative potential	Increased proliferation; avoiding senescence	Inactivation of tumor suppressors like pRb and p53; telomere maintenance through upregulation of telomerase	p53 peptidomimetics
Acquired capability: sustained angiogenesis	Continuous supply of nutrients through an increased vasculature	Changing the balance of angiogenesis inducers like VEGFR, fibroblast growth factor receptor (FGFR), etc., increase in integrin signaling, and reprogramming to alter cytokine balance	VEGFR inhibitors
Acquired capability: tissue invasion and metastasis	Escape the primary tumor mass and colonize a new terrain in the body where, at least initially, nutrients and space are not limiting	Alteration of cell–cell adherence molecules like cadherins and integrins, upregulation of MMPs, cytokines	HGF/cellular mesenchymal epithelial transition factor (c-MET) inhibitors
An enabling characteristic: genomic instability and mutation	Facilitation of all hallmarks	Random mutations, including chromosomal rearrangements; translocations, loss of heterozygosity, copy number alterations, etc.	PARP inhibitors in BRCA-deficient tumors
An enabling characteristic: tumor-promoting inflammation	Aids in tumor cells' acquired abilities of proliferation, invasion, and metastasis	Alteration of the TME and tumor stromal interactions, enabling proliferation, invasion, and metastasis	Selective anti-inflammatory drugs
An emerging hallmark: reprogramming energy metabolism	Support continuous cell growth and proliferation	Replacing the metabolic program that operates in most normal tissues and fuels the physiological operations of the associated cells; Warburg effect	Aerobic glycolysis inhibitors
An emerging hallmark: evading immune destruction	Active evasion by cancer cells from attacks and elimination by immune cells	Cancer cells may paralyze infiltrating CTLs and NK cells, by secreting TGF-β or other immunosuppressive factors; recruitment of inflammatory cells that are actively immunosuppressive, including regulatory T cells (Tregs) and myeloid-derived suppressor cells (MDSCs)	Immune checkpoint inhibitors anti CTLA-4 or PD-1/PDL-1 antibodies

potential, sustained angiogenesis, and invasion and metastasis—are shared in common by most and perhaps all types of human cancers. The two enabling characteristics, viz., genomic instability and inflammation, are crucial to the acquisition of the six hallmark capabilities and to two new "emerging hallmark" capabilities that include reprogramming energy metabolism and evading immune destruction. The latter involves the interaction of tumor cells with the tumor microenvironment (TME) to influence its constitution and signaling interactions with the surrounding stromal cells. These suggested hallmarks and capabilities of cancers were sought for their systematic use in designing effective treatments in the last decade. The major biological mechanisms that aid in the acquired, enabling, and emerging tumor hallmarks include oncogene addiction, inactivation of tumor suppressors, abnormal regulation of gene expression, escape from cell cycle checkpoints, deregulated DNA damage and repair, immune destruction, metabolic reprogramming, and acquisition of invasive and metastatic abilities. An interplay of all these mechanisms along with their contribution to developing effective treatment modalities in cancer is discussed in the subsequent sections.

3 Biological Underpinnings of the Cancer Hallmarks

3.1 Oncogenes and Tumor Suppressor Genes

In an extremely fundamental sense, cancer is a genetic disease. Two types of genetic mutations, namely, gain of function in oncogenes (oncogene addiction) and loss of function in tumor suppressor genes (TSGs), form important molecular bases of carcinogenesis, mainly through downstream effects on cell proliferation and avoidance of programmed cell death (apoptosis). Additionally, through highly interconnected signaling networks, these genes regulate multiple hallmarks of cancer.

3.1.1 Oncogene Addiction/Aberrant Cell Signaling

The term "oncogene addiction" was first coined by Dr. Bernard Weinstein to describe the reliance of tumor cells on a specific oncogenic protein or oncogenic pathway for their proliferation, survival, and malignancy [4]. Designation of "oncogene" is assigned to a specific set of genes after several preclinical and clinical "proof-of-concept" validation studies. Identification of oncogenes and their mechanistic studies has helped develop novel and effective therapies that target and restrict both tumor growth and spread [5]. Oncogene addiction is primarily characterized by abnormal production of growth-promoting signals that regulate the entry and progression of cells through the cell growth and division cycle that is otherwise strictly regulated in normal tissue cells. This leads to a loss of cell homeostasis, normal tissue architecture, and function. Oncogenic signals are generally conveyed through kinases that act as major signal transducers governing a variety of cellular activities such as metabolism, transcription, cell cycle progression, cytoskeletal rearrangement and cell movement, apoptosis, and differentiation. A major fraction of the oncogenic drivers is comprised of receptor kinases that include receptor tyrosine kinases (RTKs) like endothelial growth factor receptor (EGFR), vascular endothelial growth factor receptor (VEGFR), etc. and serine/threonine kinases (STKs) like phosphoinositide 3-kinase (PI3K), mammalian target of rapamycin (mTOR), etc. Non-receptor tyrosine kinases that act as signal transducers include c-Abl, Src, Janus-activated kinases (JAKs), focal adhesion kinases (FAKs), etc. Whilst RTKs are activated through extracellular mitogenic signals, non-receptor tyrosine kinases, located both in the cytosol and nucleus, are activated by intracellular signals [6, 7]. Mutations and dysregulation of oncogenic protein kinases are implicated in the development and progression of various cancers. The mechanisms of aberrant oncogenic signaling in cancer cells include overexpression of receptors or their cognate ligands, gene amplification, mutations, chromosomal rearrangements, and autocrine (expression of growth factor ligands) and paracrine (relay of signals through tumor-associated stroma) signaling [8, 9].

A good clinical example of oncogene addiction is chronic myelogenous leukemia (CML). CML is driven by the Bcr-Abl mutant oncogene, produced as a result of chromosome 9:22 translocation (Philadelphia chromosome). Addiction of CML to Bcr-Abl was demonstrated by the clinical success of the Bcr-Abl kinase inhibitor imatinib in CML patients [10]. This success proved the proof of concept of the effectiveness of molecular targeting, thus giving a thrust to the translational research in the area of oncogene addiction. This subsequently led to the emergence of several targeted anticancer therapies based on the study of oncogene addiction. Several successful drugs have emerged in the last two decades based on oncogene addiction: RTK inhibitors like erlotinib (EGFR), bevacizumab (VEGFR), trastuzumab [human epidermal growth factor receptor 2 (HER2)], crizotinib [anaplastic lymphoma kinase (ALK)], etc.; STK inhibitors like everolimus (mTOR), vemurafenib (B-RAF), etc.; and non-receptor kinase inhibitors like imatinib (Bcr-Abl), tofacitinib (JAK), etc. Molecular medicine based on oncogene addiction is now an accepted norm in cancer treatment and has been highly successful in several cancers. A few examples based on clinical success through oncogenic targeting is listed in Table 2.

Table 2 Examples of RTK-targeted molecular cancer therapies

Inhibitor	Target	Approved for
Trastuzumab (Herceptin)	HER2	HER2-positive breast cancer
Cetuximab (Erbitux) Panitumumab (Vectibix)	EGFR	Metastatic colorectal cancer (RAS wild-type) Metastatic non-small cell lung carcinoma (NSCLC)
Gefitinib (Iressa) Erlotinib (Tarceva)	EGFR	Metastatic colorectal cancer (RAS wild-type) Metastatic NSCLC
Lapatinib (Tykerb)	EGFR and HER2	HER2-positive breast cancer (Trastuzumab-resistant)
Bevacizumab (Avastin)	VEGFR	Metastatic colorectal cancer (mCRC)

3.1.2 Tumor Suppressors

Tumor suppressor genes are defined as a set of genes whose loss of function results in the promotion of tumor growth and malignancy. The products of TSGs classified as tumor suppressor proteins negatively regulate cell growth or promote cell death, thus restricting the potential for tumor formation. Thus, inactivation of tumor suppressor genes through genetic alterations or dysregulation can lead to unregulated cell growth and tumor development. Most tumor suppressor genes follow the characteristic “two-hit” hypothesis proposed by Alfred Knudson, which states that both gene alleles must be lost to unmask the malignant phenotype [11]. Mutations or loss of heterozygosity (LOH) are the most common molecular alterations in tumor suppressor genes, leading to loss of tumor suppressor activity. In addition to these, tumor suppressor genes can be functionally inactivated through epigenetic modulation (e.g., methylation) of the gene promoter that causes its transcription, proteasome-mediated degradation, or aberrant interacting proteins [12]. The most commonly encountered aberrant tumor suppressor genes in cancers include the cell cycle regulatory protein retinoblastoma (Rb) susceptibility gene, p53, breast cancer susceptibility genes (BRCA 1 and 2), and phosphatase and tensin homologue deleted on chromosome 10 (PTEN).

Retinoblastoma (Rb) Suppressors

The Rb or retinoblastoma susceptibility gene was the first tumor suppressor gene to be identified and characterized. Retinoblastoma is a rare childhood eye tumor. It can be either familial (hereditary) or sporadic (nonhereditary) [13]. The Rb protein is encoded by the RB1 gene located on chromosome 13 (13q14.1–q14.2 locus). It is a universal cell cycle regulator with a central role in governing the passage of cells through the G1 phase as described in the section “The cyclin–CDK–Rb Axis.” Rb binds and inhibits E2 promoter binding factor–dimerization partner (E2F–DP) dimers. E2Fs are transcription factors (TFs) that regulate genes involved in G1–S- and S-phase progression of the cell cycle [cyclin E, cyclin A, proliferating cell nuclear antigen (PCNA)]. By keeping E2F–DP inactivated, RB1 restricts the cell in the G1 phase, acting as a growth suppressor, and, hence, is also referred to as “the restriction point of cell cycle control” [14]. The Rb–E2F–DP complex also attracts a histone deacetylase (HDAC) protein to the chromatin, reducing transcription of the S phase-promoting factors, further suppressing DNA synthesis. In addition to its role in restricting cell cycle progression in association with the E2F transcription factor, Rb can regulate senescence, chromosomal segregation, checkpoint controls, apoptosis, and terminal differentiation of cells through posttranslational modifications (acetylation, methylation, etc.) [15–18]. The most common strategy applied in translational research for restoration of Rb suppressor function is maintenance of the E2F–Rb complex. In this direction, several cyclin-dependent kinase inhibitors (CDKi) (flavopiridol, palbociclib, ribociclib, roscovitine, etc.) have been designed and are at different phases of clinical trials or are approved for use, as listed in Table 5. Similarly, Rb deficiency is linked to overexpression of the G2–M checkpoints. Hence, targeting CHK1, polo-like kinase 1 (PLK1), etc. may abrogate the downstream pathways of cell cycle progression and prove beneficial in treating Rb-deficient tumors [19].

The p53 Gene

The tumor suppressor p53 is a pivotal protein in the maintenance of genomic integrity. It is appropriately called the “guardian of the genome” [20]. This protein is encoded by the TP53 gene located on chromosome 17 (17p13.1 locus). In addition to the full-length protein, at least 12 protein isoforms (p53 isoforms), ranging in size from 3.5 to 43.7 kDa, are encoded by the human TP53 gene [21]. p63 and p73 are other tumor suppressor proteins belonging to the p53 family. These proteins are involved in cellular responses to stress and development and share significant structural and functional homologies with p53, particularly in the DNA-binding domain (DBD) [22, 23]. p53 is the most commonly mutated gene in cancer with mutations detected in approximately 50% of all human cancers [20]. Germline p53 mutations are associated with Li–Fraumeni syndrome, a hereditary predisposition linked to several cancers [24]. The biological role of p53 is primarily attributed to its activity as a transcription factor, with most pathogenic p53 mutations being found in the DNA-binding domain (DBD) of the protein. Other p53 mutations largely influence its nuclear localization, oligomerization, and transactivation functions [25, 26].

Under normal conditions, p53 has an extremely short half-life (approximately 20 min) and a low steady-state protein level. It is maintained in an inactive state by binding to its negative regulator protein, the mouse double minute 2 (MDM2) ligase. In response to DNA damage or other cellular stress signals (e.g., nutrient deprivation, hypoxia, etc.), p53 is stabilized through inactivation of MDM2 to perform its tumor suppressor role [26]. Activated p53 acts as a transcription factor transcribing a number of genes, including the CDKi p21. It causes arrest of the cell cycle in the G1 or G2 phase to allow for DNA repair, as shown in Fig. 1. It can also contribute to DNA damage repair by activating genes that facilitate single-strand breaks (SSBs) of repair pathways [nucleotide excision repair (NER) and base excision repair (BER)] through its interaction with apurinic/apyrimidinic (AP) endonuclease (APE) and DNA polymerase-β (polβ) [28, 29]. In response to severe DNA damage, p53 functions to redirect the cell into a permanent cell cycle arrest, senescence, and apoptosis. Additionally, p53 is also implicated in the regulation of angiogenesis and metastasis. p53-regulated angiogenesis and metastasis regulators include the tumor suppressor protein maspin, hypermethylated in cancer (HIC-1) proteins, and the metastasis suppressor protein Kangai-1 (KAI-1) [30–32]. Other functions of p53 include regulation of glycolysis and reactive oxygen species (ROS) that contribute to its tumor suppression effect by influencing the emerging hallmarks of cancer, viz., metabolism and tumor–tumor microenvironment (TME) interaction, respectively [33]. p53 is also capable of interacting with other cellular pathways [e.g., PI3K, B-cell lymphoma 2 (BCL-2), survivin, myeloid cell leukemia-1 (MCL-1), insulin-like growth factor (IGFR), etc.] to trigger apoptosis or cellular differentiation [34]. Due to its pleiotropic role in the regulation of numerous cellular functions, various strategies have been used to restore its tumor suppressor functions. In this direction, gene therapy and supplementation with the p53 peptide strategy has resulted in a phase II clinical trial with a p53 peptide vaccine with or without interleukin-2 (IL-2) (NCI-99-C-0138) and in a phase II study of Ad5CMV-p53 gene therapy (INGN 201) plus docetaxel [35]. Other strategies that can be employed to effectively restore p53 functions include activation and restoration of wild-type (WT) p53, reactivation of p53 activity through conformational changes in the mutant p53 structure, depletion of mutant p53, targeting of proteins that negatively interact with p53, bypassing the requirement for upstream p53 activation [Bcl-2 homology 3 (BH3) mimetics, e.g., ABT-737], synthetic lethality approach with cell cycle regulatory proteins like CHK1, WEE1, PLK, etc., and inhibition of pathways activated downstream of mutant p53 [35, 36]. Pharmacological targeting has shown success in preclinical studies, and several inhibitors have entered into clinical trials. APR-246 is a first-in-class agent targeting mutant p53, leading to reexpression of wild-type p53 activity. It has shown efficacy against a broad range of p53 mutations (ClinicalTrials.gov identifier: NCT03745716). It is a prodrug that gets metabolized to methylene quinuclidinone (MQ), which acts as the active drug. MQ acts by covalently linking the thiol groups on cysteine residues in the p53 core domain. This results in a conformational change in the p53 protein, leading to restoration of its tumor suppressor function. Similarly, COTI-2 is an orally bioavailable compound that restores p53 tumor suppressor function by inducing conformational changes in the mutant p53. It is a Food and Drug Administration (FDA)-designated orphan drug for treatment of ovarian cancer (http://cotingapharma.com/pipeline/coti-2/). WR1065, a derivative of the radioprotectant drug amifostine activates p53 through a DNA damage-independent and redox-dependent mechanism [37]. Similarly, repositioning of several compounds [arsenic trioxide, statins, histone deacetylase (HDAC) inhibitors, etc.], which can block p53 oncogenic activity by depletion of p53 mutant function, is being investigated [35, 36]. Another strategy that has shown promise in preclinical studies involves prevention of premature termination of TP53-messenger RNA (mRNA) translation, resulting from nonsense mutations. This involves use of high concentrations of aminoglycosides that can restore gene function by allowing premature termination codon read-through and thus restoring active proteins resulting from genetic defects caused by nonsense mutations. CDX5–1 is an example of one such compound that specifically restores p53 functional protein when used in combination with aminoglycosides [38]. A summary of strategies targeting p53 is provided in Table 3 [35–38].

Breast Cancer Susceptibility Genes: BRCA1 and BRCA2

In the 1990s, BRCA1 and BRCA2 were discovered in Mary-Claire King's Laboratory at UC Berkeley and subsequently characterized as breast cancer susceptibility genes predis-

Table 3 Strategies targeted at restoration of p53 function [35–38]

Strategy	Compounds	Clinical trial status
Wild-type p53 restoration and activation	MDM2 inhibitors (idasanutlin, benzodiazepinone)	Idasanutlin, phase 1 (NCT03362723)
p53 peptides for restoration of p53 levels	Modified vaccinia virus Ankara expressing p53	Phase 1 (NCT02275039)
p53 gene therapy for restoration of p53 levels	Adenoviral human p53 gene (rAd-p53)	Phase 2 (NCT02561546)
p53 synthetic long peptide vaccine	p53-SLP vaccine	Phase 2 (NCT00844506)
Dendritic cell-based p53 vaccine	Ad.-p53 DC	Phase 2 (NCT03406715)
Pharmacological inhibitors to rescue mutant p53 conformation and function to restore wild-type p53 activity	PRIMA-1MET (APR-246)	Phase 1 (NCT03072043, NCT02999893)
	WR-1065 or RadProtect®	Phase I (NCT02587442)
	COTI-2	Phase I (NCT02433626)
Depletion of mutant p53	Arsenic trioxide Approved for acute promyelocytic leukemia (APL)	Phase 2 (NCT01428128)
	SAHA (histone deacetylase (HDAC) inhibitor) Approved for the treatment of cutaneous T-cell lymphoma	Phase 1 (NCT02042989) phase 2 (NCT00121225)
	Disulfiram (DSF)	Phase 1 (NCT01907165)
	Heat shock protein (HSP) 90 inhibitors (geldanamycin)	Phase 2 (NCT00093405)
Alteration of proteins that interact with, stabilize, and/or contribute to the oncogenic activity of mutant p53	All-*trans* retinoic acid (ATRA)	FDA-approved for the treatment of APML
Inhibiting pathways activated downstream of mutant p53	Statins, metformin	Approved drugs for repositioning in cancer treatment
	Sunitinib, PARP inhibitors, proteasome inhibitors	Approved drugs
Synthetic lethality approaches	UCN-01 (CHK1 inhibitor)	Phase 2 (NCT00045747)
Targeting the downstream pathways of mutant p53	WEE1 inhibitors (such as PD0166285 and AZD1775)	Phase 1 (NCT02906059) and phase 2 (NCT02593019)
	BI-2536 (and other polo-like kinase 1 (PLK1) inhibitors)	Phase 1 (NCT02211872) and phase 2 (NCT00706498)
Preventing premature termination of TP53-mRNA translation owing to nonsense mutations	CDX5–1 plus aminoglycoside antibiotics	Preclinical

posing carriers to breast, ovarian, and other cancers. The BRCA1 gene is located on chromosome 17 locus 17q21, whereas BRCA2 is located on chromosome 13 locus 13q12. The BRCA1 or BRCA2 mutation carriers have a lifetime breast cancer risk of 50–80% and a lifetime ovarian cancer risk of 10–20% [39, 40]. These genes are referred to as "caretakers" of the human genome since deficient cells tend to accumulate DNA damage, leading to oncogenesis. These lesions include chromosomal breaks, aberrant mitotic exchanges, and abnormal DNA ploidy [41].

BRCA1 is a nuclear phosphoprotein and an essential component of the cellular DNA damage repair (DDR) machinery. It binds to the DDR sensor Mre11, Rad50, Nbs1 (MRN) complex and guides the localization of the recombinase RAD51 to the damaged DNA foci to mediate DDR in response to double-strand breaks (DSBs) [42–44]. Similar to BRCA1, BRCA2 is also a nuclear phosphoprotein that binds to RAD51 and MRE11 to regulate DSB repair and maintain chromosomal integrity [44]. Homologous recombination (HR) and Non-homologous end joining (NHEJ) are the two major mechanisms of DSB repair in mammalian cells. Non-homologous end joining is an error-prone repair mechanism that does not require a complementary sister chromatid and functions at the G1 phase, whereas the error-free homologous recombination repair occurs by ligation of homologous sister chromatids during the S and G2 phases [45]. BRCA gene products are essential for the homologous recombination repair mechanism. They serve as a scaffold protein to integrate different components of the homologous recombination machinery [replication protein A (RPA), X-ray repair cross-complementing 1 (XRCC1), polβ, etc.] as well as resection of 5′-end of double-strand breaks [46]. In addition to DNA repair, BRCA1 also has important roles in transcriptional regulation, differentiation, and ubiquitination as an E3 ligase [47, 48]. Therapeutically, a deficient homologous recombination repair abnormality has been targeted using a synthetic lethal targeting strategy with poly (ADP-ribose) polymerase (PARP) inhibitors and several PARP inhibitors (olaparib, rucaparib, etc.) are approved in the treatment of ovarian and breast cancers [49].

Phosphatase and Tensin Homologue Deleted on Chromosome 10 (PTEN)

Phosphatase and tensin homologue deleted on chromosome 10 (PTEN) is a tumor suppressor that is mutated or lost in several cancers [50]. The protein is encoded by the PTEN gene on chromosome 10 (locus 10q23). It is a lipid phosphatase that catalytically dephosphorylates phosphatidylinositol-3,4,5-trisphosphate (PIP3), which, in turn, is a potent activator of the AKT kinase in the PI3K–AKT–mTOR pathway. PTEN germline mutations are observed in 60–80% of patients with PTEN hamartoma tumor syndrome (PHTS) or Cowden syndrome [51]. Somatic mutations in PTEN are found in a wide variety of tumors (breast, prostate, glioma, melanoma) [51]. A loss of PTEN function leads to increased expression of the PI3K–AKT pathway, which is the major cellular pathway regulating numerous hallmarks of cancer, including cell proliferation, survival, angiogenesis, metastasis, and metabolism [52]. Numerous cellular functions are regulated by PTEN. It acts as a cell cycle regulator through its ability to reduce cyclin D1 levels and increases CDKi p27 via its lipid phosphatase activity, thus preventing cell cycle progression [53]. Cytoplasmic PTEN is primarily involved in regulating PI3K–AKT signaling, regulation of proliferation, and cellular metabolism, whereas nuclear PTEN regulates chromosomal stability, DNA repair, and apoptosis. Nuclear PTEN is reported to interact with centromere binding protein C (CENP-C), an essential component for centromeric stability, and induces RAD51, which is involved in DNA double-strand break repair [54, 55]. It also binds to the anaphase-promoting complex (APC), thus regulating DNA stability, replication, and repair. The APC/C^{CDH1} (cyclosome) complex is active during mitosis, and its substrates include cyclins (cyclins A and B), kinases (Aurora kinases, PLK1), chromosomal segregation proteins (Securin, SGO1), DNA replication proteins (Geminin, Cdc6), an F-box protein (SKP2), and transcription factors (Ets2, FoxM1) [56].

Therapeutic strategies targeting cancers with loss of PTEN function include targeting the PI3K pathway kinases, namely, the PI3K and mTOR inhibitors. A number of PI3K inhibitors are in clinical trials and include BEZ235, BGT226, etc. Several mTOR inhibitors are approved anticancer drugs and include everolimus, temsirolimus, etc. Due to their role in the maintenance of genomic stability, PTEN-deficient tumors can also be targeted with DNA damage response inhibitors such as PARP inhibitors (olaparib, rucaparib, etc.), PLK, WEE-1, etc. Other therapeutic strategies that have been proposed to target tumors with PTEN loss include use of statins that promote the activity of the transcription factor peroxisome proliferator-activated receptor-gamma (PPARγ), which, in turn, upregulates PTEN mRNA levels and hence its expression. Since PTEN is also rendered inactive through epigenetic modifications like methylation, epigenetic modulators like DNA methyltransferase (DNMT) inhibitors such as azacytidine may restore its expression. In a preclinical study, restoration of the PTEN level was achieved using the mRNA of the PTEN pseudogene PTENP1 to sequester microRNAs (miRNAs) that repress PTEN translation [35, 57, 58].

3.2 Regulation of Gene Expression

Genetic aberration is a common feature of cancer, and random mutations, including chromosomal rearrangements, translocations, loss of heterozygosity (LOH), and copy number alterations, are commonly encountered in oncogenes and tumor suppressors. Normal gene expression is regulated through various epigenetic, transcriptional, posttranscriptional, translation, or posttranslational mechanisms, several of which are found to be altered in cancer. Regulation of gene expression in all cells is primarily mediated at the transcription initiation step. The transcription control center can lie in the promoter (binding site for RNA polymerase II), enhancer, or silencer sequences. Transcription factors (TFs) are proteins or protein complexes that are the final effectors of signal transduction pathways, which transduce the proliferation signals elicited by growth factors. Transcription factors can bind directly to the promoter region of a DNA or RNA polymerase molecule. Chromatin modulation through epigenetic modification is an additional mechanism of gene expression regulation. The switching between inactive and active chromatin mediated by epigenetic events include histone modifications like demethylation and acetylation.

Transcriptional dysregulation in cancer can be a result of disease-defining genetic alterations. These alterations can regulate transcription factors indirectly through mutation of converging signaling factors or directly through genetic alterations in transcription factors or transcriptional machinery components like signaling proteins, cofactors, chromatin regulators, chromosome-structuring proteins, or *cis*-elements (Table 4) [59]. Increasingly, molecular regulators of transcriptional control are being explored as attractive anticancer targets. In this direction, inhibition of an oncogenic transcription factor, promyelocytic leukemia/retinoic acid receptor alpha (PML–RARA), by all-*trans* retinoic acid (ATRA)

Table 4 Components of gene expression regulators dysregulated in cancer [59]

Component	Role	Gene/gene product
Cis-elements	Enhancers	TAL1, LMO2
	Promoters	TERT
	Insulators	TAL1
Transcription factors (TFs)	Master or lineage TF	RUNX1, TAL1, WT1, HOX
	Proliferation TF	MYC, p53
	Signaling TF	STAT3, NOTCH, RAR, AR, ER
Transcriptional coactivators	Mediator complex	MED12
	Cohesin complex	STAG2, SMC3
	Cyclin-dependent kinase	CDK12
Chromatin regulators	Histone writers	EZH2, P300/CBP, MLL1–4, SETD2
	Histone readers	BRD4, TRIM33, ING1
	Histone erasers	JARID1A, UTX
	Chromatin remodelers	SS18
RNA polymerase II		Q403, L438_H439del
Histones		H3K27M, H3K36M, H3K79

has shown clinical benefit as treatment for acute promyelocytic leukemia (APML) [60]. Other strategies for targeting transcription factors and their control machinery include bromodomain-containing protein 4 (BRD4) inhibitors (e.g., JQ1) in NUT midline carcinoma [61, 62], inhibition of CDKs (CDK7, CDK12) that govern RNA pol II activity [63], inhibition of disruptor of telomeric silencing 1-like (DOT1L) histone methyltransferase that controls transcriptional activity by demethylating H3K79 [64], chromatin regulators such as histone demethylases (KDM5A) and histone deacetylases (HDACs) [65], etc.

3.3 Dysregulation of Cell Cycle Checkpoints

Cell cycle regulation is an essential feature in the maintenance of tissue homeostasis. Disruption of the normal cell cycle leads to unchecked cell proliferation, growth, and disturbance of the normal tissue architecture. The cell cycle comprises a coordinated series of events that carry cells from their quiescence/resting state (G0) to proliferation while maintaining their genetic constitution. It consists of four distinct phases: G1, S, G2, and M [66]. The S or the DNA synthesis phase and the M or the mitotic phase are separated from each other by the gap phases G1 and G2. Entry into the cell cycle (G1) from G0 occurs in response to a mitogenic stimulus usually through an upstream receptor tyrosine kinase. Regulation of transition through the various cell cycle phases occurs through coordinated expression of proteins called cyclin-dependent kinases (CDKs) and their associated partner proteins called cyclins. The expression of specific cyclin/CDK pairs regulates either the transition or non-transition of cells in a particular cell cycle phase, as shown in Fig. 1. In addition to regulation by the CDKs/cyclins, cell cycle progression is also monitored through checkpoint proteins that are primarily activated in response to DNA damage as well as signaling through tumor suppressor and antiapoptotic proteins. These so-called checkpoints exist at G1–S, intra-S, and G2–M transition phases [67]. The cumulative effect of these regulatory checkpoints and their interactions decide cell fate: to undergo proliferation or apoptosis. Cells can also exit the cell cycle and enter a reversible or permanent cell cycle arrest (the G1 or G2 phase) or senescence.

3.3.1 The Cyclin–CDK–Rb Axis

Nine CDKs (CDK1–9) and cyclins (A–T) regulate different processes in the cell cycle through formation of specific cyclin/CDK complexes. Progression of cell cycle phases is regulated by sequential synthesis and degradation of CDK partner cyclins. Cell cycle progression is negatively regulated by CDKi that inhibit cyclin/CDK complex activity. The CDKi belongs to either the INK4 (p16Ink4a, p15Ink4b, p18Ink4c, and p19Ink4) or CIP/KIP (p21Waf1, p27Kip1, and p57Kip2) family of proteins that target specific cyclin/CDK complexes. The INK4 CDKi binds to CDK4/6 and blocks their association with D-type cyclins, inactivating the kinase activity of CDK4 and CDK6. Similarly, the CIP/KIP CDKi binds and inhibits the kinase activity of CDK2 and CDK1, thus maintaining cellular homeostasis. The CDKis are, in turn, positively regulated by various tumor suppressor proteins—p53, SMAD4, etc. [66, 67].

Initiation of cell cycle progression from G0 to G1 starts with activation of the cyclin D/CDK4/6 complex, which acts by two major mechanisms: first, by sequestering the CDKis p21CIP1 and p27KIP1 and, second, by phosphorylating various cellular targets, including the retinoblastoma (Rb) tumor suppressor protein [14]. Closely related Rb proteins that include RBL1 or p107 and RBL2 or p130 can also be phosphorylated by this complex. These phosphorylation events lead to activation of the cyclin–CDK–Rb pathway that ends with activation of the transcription factor E2F. In its active state (tumor suppressive function), Rb is hypophosphorylated and inhibits the transcription factor E2F by binding to it. Phosphorylation of Rb by cyclin D/CDK4/6 releases E2F that, in turn, transcribes a group of genes involved in cell cycle progression from the G1 into the S phase. Included amongst these genes are cyclin E1 (CCNE1) and cyclin E2 (CCNE2) that drive the progression of cells from the G1 to the S phase. Other genes transcribed by E2F regulate DNA replication, chromatin structure, chromosomal segregation, spindle assembly checkpoint (SAC), centromere organization proteins, etc. during progression of the S phase. Cyclin E1/E2 bind to and activate CDK2. Cyclin E–CDK2 complexes further phosphorylate Rb. This hyperphosphorylation event serves as a positive feedback loop, further driving the cell cycle [67]. Thus, the cyclin D1–CDK4/6–Rb axis drives progression through the G1 stage and the cyclin E–CDK2–Rb axis drives the S-phase transition and progression. Negative regulators of the cyclin E–CDK2 complexes include p27KIP1 and p21CIP1 that, in turn, are regulated by growth-inhibitory signals and the p53-dependent G1 DNA damage checkpoint CHK2. Progression from the G2 phase to mitosis (the M phase) is controlled by cyclin A2/CDK1 and cyclin B/CDK1 complexes. During the G2 phase, CDK1 binds to and becomes activated by cyclin A2 and cyclin B. Upon entry into mitosis, cyclin A2 is degraded and CDK1 activity is maintained in complexes with B-type cyclins. The CDK1 kinase is essential for mitotic entry and several mitotic events. B-type cyclins are degraded by the anaphase-promoting complex/cyclosome (APC/C) in late mitosis, leading to the termination of the mitotic phase [27, 68]. Inactivation of CDK1 through degradation of cyclin B enables chromosomal separation and cytokinesis, thus completing the cell cycle. At the G2 phase, CDK1 activity is regulated through kinases MYT1 and WEE1, which, in turn, are negatively regulated by CDC25 phosphatases [69, 70]. The non-cycle CDK/cyclin complexes include CDK5 (cyclin D/E/G), CDK7 (cyclin H), and CDK9 (cyclin T, K). These kinases function to regulate senescence, CDK-activating kinase transcription, and transcription of pro-proliferative proteins, respectively [67, 71].

3.3.2 DNA Damage Response Checkpoints

DNA damage response during any phase of the cell cycle is initiated with the detection of DNA damage by sensor proteins. Cells have specific DNA damage response checkpoints that halt cell cycle progression till DNA repair is accomplished. A majority of these DNA damage checkpoints influence the activity of specific CDK complexes, as shown in Fig. 2 [71]. Depending on the type of DNA damage, the sensor proteins that include the MRE11–RAD50–NBS1(MRN) complex, RAD17, etc. activate the transducer proteins (e.g., ATM, ATR, etc.) that, in turn, transduce the signal to effector proteins—checkpoint kinase 1 (CHK1) and CHK2. Activated CHKs, in turn, switch "on" a cascade of events, leading to cell cycle arrest, apoptosis, DNA repair, and/or activation of DNA damage-induced transcription machinery. In the absence of an efficient checkpoint system, unrepaired damages go undetected, leading to mutations and genomic instability that supports oncogenesis.

Each step in DDR is tightly regulated. Kinases belonging to the phosphatidylinositol-3-kinase (PI3K) superfamily ataxia-telangiectasia mutated kinase (ATM); ATM- and Rad3-related kinase (ATR); and DNA-dependent protein kinase (DNA-PK) catalytic subunit are the primary transducers of DDR. On activation by phosphorylation, both ATM and ATR act as regulators of the DDR by affecting DNA replication, DNA repair, DNA recombination, transcription, and protein metabolism and cell cycle progression. DNA-PK interacts with the DNA-binding Ku 70/80 heterodimer, pushing the cells to undergo DNA repair via the non-homologous end joining (NHEJ) repair pathway with consequent introduction of erroneous DNA that may support oncogenesis. ATM and ATR protein kinases phosphorylate and activate the effector kinases—checkpoint kinase 1 (CHK1) and CHK2—which, in turn, phosphorylate their downstream target proteins that include p53, MYT1, CDC25, etc. [71–73].

DNA damage effector checkpoints CHK2 and CHK1 act at the G1–S and G2–M transition phases, respectively [71]. At the G1–S transition, downstream activation of the tumor suppressor p53 via CHK2 induces expression of the CDKi p21CIP1 that, in turn, inhibits cyclin E–CDK2 or cyclin A/B–CDK1 complexes, leading to G1 or G2 arrest. Progression from the G2 to the M phase is regulated by activation of cyclin A/B–CDK1 complex that requires phosphorylation at threonine. Activation of the cyclin B–CDK1 kinase requires dephosphorylation of CDK1 at Thr14 and Tyr15, and phosphorylation at Thr161 is mediated by CDC25 phosphatase and cyclin H/CDK7, respectively. At the G2–M checkpoint, CHK1 kinase suppresses CDC25 phosphatase activity, resulting in the simultaneous activation of Myt1 and WEE1, both of which mediate temporary S-phase arrest through the G2 checkpoint by phosphorylation of CDC25A, CDC25B, CDC25C, and CDK1 inactivation, thus allowing cells to repair the DNA damage (see Fig. 2). CHK1 is thus negatively regulated by the CDC25 phosphatase that inacti-

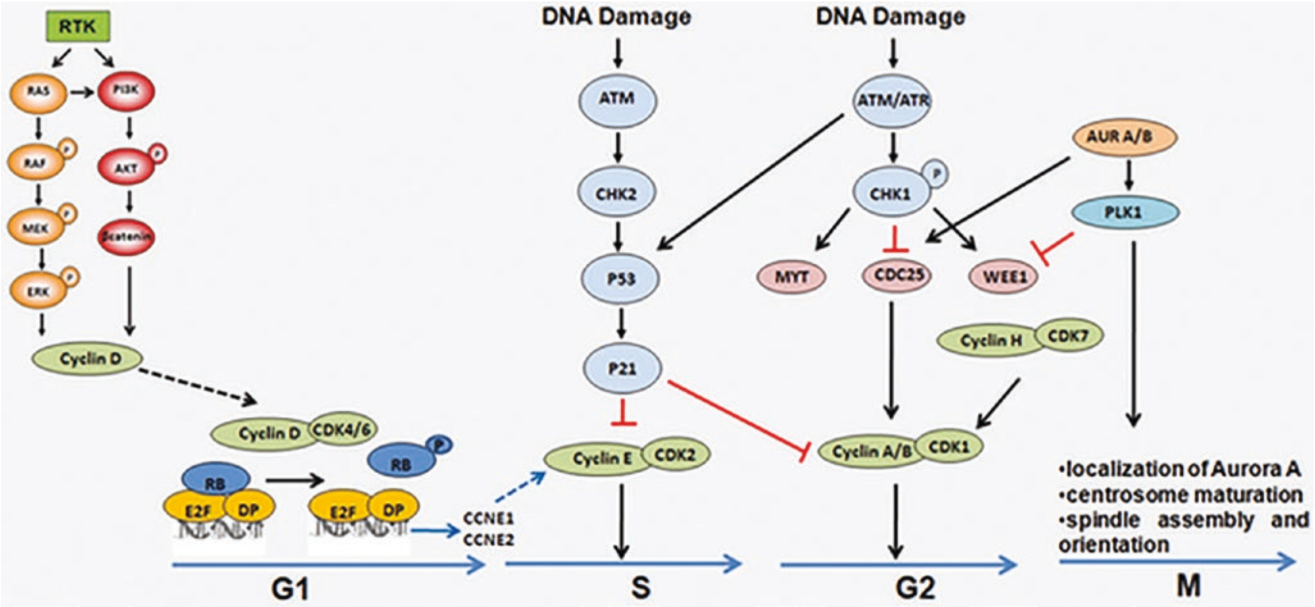

Fig. 2 Regulation of cell cycle progression and the role of DDR [67, 71]

vates Myt and WEE1 by dephosphorylation, thus releasing the negative proliferation controls on cyclin A/B–CDK1 complexes and allowing cell cycle progression. Inhibition of CHK1, WEE1, or MYT1 in cancer cells prevents cell cycle arrest during the S or G2 phase and enables cell proliferation despite accumulation of DNA damage that can lead to mitotic catastrophe and cell death during the M phase [74]. Positive regulation of CDK1 is mediated via polo-like kinase 1 (PLK1) and Aurora kinases. PLK1 activates CDK1 by suppression of CHK1 activity through phosphorylation-dependent degradation of WEE1 and activation of CDC25. PLK1, in turn, is regulated by Aurora A kinase, thereby promoting CDK1 activation and mitotic entry overcoming the G2–M checkpoint. Aurora kinases are serine/threonine kinases that regulate mitosis and cytokinesis. Aurora A localizes to the centrosomes, starting in the S phase, and is essential for centrosome maturation, spindle assembly, and spindle orientation in the M phase. Additionally, it stabilizes the transcription factor NMYC (encoded by MYCN) by preventing its proteasomal degradation and thereby promotes G1–S progression. Aurora B localizes at chromosomes and at the mitotic spindle during the M phase, where it constitutes a part of the chromosomal passenger complex (CPC). Aurora B controls chromosomal condensation and orientation as well as proper execution of cytokinesis. Bypass of the G2–M DNA damage checkpoint through Aurora kinase-mediated PLK activation leads to cellular mitotic catastrophe in the resultant phenotype [74–76].

In most cancer cells, the G1–S checkpoint CHK2 is dysregulated, leading to bypass of this check signal and continuation of the cells into the S phase before repair of the damaged DNA. This gives cancer cells a means to accumulate oncogenic mutations that favor proliferation and evasion of apoptosis. In the absence of the G1–S checkpoint, cancer cells are dependent on the G2–M checkpoint to prevent excessive DNA damage that may lead to apoptosis via mitotic catastrophe. The G2–M checkpoint thus works in favor of tumor cell survival, and, hence, inhibition of the G2–M checkpoint will prove detrimental to tumor cells [77, 78]. Such a drug target strategy will also provide for a higher therapeutic index as it will selectively target tumor cells with sparing of normal cells that have functional G1 and G2–M checkpoints. In addition to the G2–M checkpoint, G2–M regulatory kinases—Aurora kinases, PLK, WEE1 that participate in DDR—serve as attractive targets in cancer [79].

Given their role in the regulation of proliferation, several cell cycle checkpoint proteins have been used to obtain therapeutic drugs, examples of which are provided in Table 5 [71, 77–79].

Table 5 Cell cycle regulators in clinical development

Drugs	Target	Clinical trial status
Dinaciclib	CDK2, CDK5, CDK1, CDK9, CDK7, CDK6	Phase III: chronic lymphocytic leukemia (CLL) Phase II: Melanoma, CLL, lung, breast, and multiple myeloma
R-roscovitine (seliciclib)	CDK2, CDK7, CDK1, ERK2	Phase I: Advanced solid tumors
Palbociclib (PD0332991)	CDK4, CDK6	Approved for HER2-negative breast cancer in combination with aromatase inhibitors
Abemaciclib	CDK4, CDK6	Approved for hormone receptor-positive, HER2-negative advanced metastatic breast cancer both in combination with fulvestrant and as a monotherapy
Ribociclib (LEE011)	CDK4, CDK6	Approved as a combination therapy with aromatase inhibitors for indications similar to those of palbociclib
MK-8776 (Scheme 900776)	CHK1, CDK2, PIM1	Phase II: AML Phase I: Non-Hodgkin's lymphoma
LY2606368	CHK1, CHK2, RSK1, MELK, SIK, BRSK2, and ARK5 (64 nM)	Phase II: Breast, ovarian, prostate, and lung Phase I: Head and neck, AML, and Myelodysplastic syndrome (MDS)
AZD1775 (MK-1775)	WEE1, YES1	Phase II: Lung, ovarian, pancreatic, stomach, AML, MDS, and head and neck Phase I: Head and neck, glioma, pancreatic, cervical, CML, AML, and bladder
Rigosertib (ON 01910. Na)	PLK1, PDGFR, Bcr-Abl, FLT1, SRC, FYN, PLK2, and CDK1	Phase III: MDS and pancreatic Phase II: MDS, AML, ALL, CML, ovarian, and squamous cell
Volasertib (BI 6727)	PLK1, PLK2, and PLK3	Phase III: AML Phase II: AML, MDS, lung, ovarian, and urothelial
Alisertib (MLN8237)	Aurora A, EPHA2	Phase III: Peripheral T-cell lymphoma Phase II: Lymphoma, lung, breast, ovarian, prostate, AML, gastroesophageal, melanoma, multiple myeloma, uterine, head and neck, mesothelioma, neuroblastoma, MDS, rhabdoid, and urothelial
AMG 900	Aurora C, Aurora B, Aurora A, and p38α	Phase I: AML and advanced solid tumors

3.4 Avoiding Immune Destruction

Avoiding immune destruction is an emerging hallmark in cancer that is widely acknowledged in the process of tumorigenesis. Both tumor cell features and the tumor microenvironment (TME) can modulate immune vigilance in cancers. Tumor cell features that aid in the evasion of immune surveillance include lack of costimulatory surface molecules such as B7 for antigen presentation, resulting in T-cell anergy, reduced expression of major histocompatibility complex (MHC) class I or class II receptors, expression of FasL (Fas ligand) that aid in apoptosis of T cells, expression of mucins that mask the tumor-specific antigens and release of cytokines (TGF-β, VEGF, etc.). A progressive alteration of an immune-suppressive TME is highly regulated through inflammatory cytokines and immunosuppression by selective infiltration of regulatory T cells (Tregs). Immune surveillance can monitor and subsequently eliminate tumor cells through recognition of tumor-specific antigens or antigens that are differentially expressed between cancer and normal cells. This immune response is elicited in the form of a strong inflammatory response that results in accumulation of specific cytokines and lymphocytes (tumor-infiltrating lymphocytes) and natural killer (NK) cells at the tumor site. Inflammatory modulation of the TME may either suppress or support tumor growth depending upon the TME and tumor–TME interactions. Chronic inflammation is reported to support tumor proliferation and to play a significant role in tumor immunosuppression and T-cell proliferation. It contributes to tumor survival and proliferation, provides extracellular matrix-modifying factors that aid in angiogenesis as well as in invasion and metastasis [80]. The most notable cytokines that induce immunosuppression include VEGF and TGF-β. VEGF levels and overexpression of VEGFR, in addition to their role in angiogenesis, have emerged as notable players in the regulation of TME's immune components. Increased expression of VEGF reduces the trafficking, proliferation, and effector functions of T lymphocytes, increases differentiation, proliferation, and density of Tregs that, in turn, negatively regulate cytotoxic T (Tc) cells and thus eliminates tumor cells, increases the number of immunosuppressive tumor-associated macrophages (TAMs) and myeloid-derived suppressor cells (MDSCs), and inhibits maturation of dendritic cells that, in turn, function in the priming of T-helper (Th) cells. VEGF can also increase the expression of the checkpoint proteins (PD-1, CTLA-4, Tim-3, Lag-3) on antitumor T lymphocytes, priming these cells to targeting by the Tregs. Trafficking of immune cells and tumor–stromal cell interactions by VEGF is regulated through expression of adhesion molecules, including the integrin ligands intercellular adhesion molecule 1 (ICAM1) and vascular cell adhesion protein 1 (VCAM1), on endothelial cells (ECs) and immune cells. Hence VEGF/VEGFR inhibitors may be effective in immune targeting of tumors. Several of these agents are already approved as anticancer agents and include bevacizumab, sunitinib, etc. [81–84]. These agents in combination with immunotherapies are under various stages of clinical development (clinicaltrials.gov; NCT02348008, NCT03475004, etc.). Another cytokine TGF-β secreted by the tumor cells can bring about similar immune suppression by increasing the recruitment of Tregs and suppressing the tumor suppressive effector cells (Tc and Th) [80]. Other chemokines secreted by tumor cells, such as C–C motif chemokine ligand (CCL)2, CCL28, CXCL8, CXCL12, ANG2, PlGF, and adenosine promote the recruitment of immunosuppressive cells as well as angiogenesis, thus changing the cellular balance of the TME [85].

Cancer-related inflammation contributes not only to the evasion of the immune response by the tumor cells but also provides pro-proliferative, metastatic, and angiogenesis capabilities to the tumor through TME modulation. Hence, new therapeutic options tailored to interfere with inflammation in the TME are being tested. These strategies include reeducating the TME through metabolic targeting, inhibiting inflammatory mediators or their downstream signaling molecules, blocking the recruitment of myeloid cells, and modulating immunosuppressive functions. Cytokine therapy with interleukin-2 (IL-2) in renal cell carcinoma and with interferon (IFN)-γ and IFN-β in hairy cell leukemia and high-risk melanoma, respectively, has demonstrated clinical benefits [85]. Several cancer vaccines that can generate new antigen-specific T-cell responses and amplify existing responses have been developed and these include Sipuleucel-T, Talimogene laherparepvec (T-VEC), etc. [86]. The concept of differential expression of tumor and normal cell surface antigens forms the basis for designing monoclonal antibodies as an effective immunotherapy, for example, targeting of tumor growth factor receptor HER2 with Herceptin. Immunomodulation through "adoptive T-cell therapies" that harness the tumor-killing properties of T cells are being tested to restore antitumor immune cell population. The therapy involves isolation, expansion, and genetic engineering of autologous T cells to express tumor-specific recognition receptors that include both conventional T-cell receptors (TCRs) and synthetic constructs called chimeric antigen receptors (CARs) [87]. Destruction of an active immunosuppressive T-cell population is mediated through activation of negative regulatory pathways, also known as immune checkpoints (CTLA-4, PD1, PDL-1) by tumor cells. Targeting immune checkpoints that negatively regulate cytotoxic T cells is thus an attractive strategy to maintain a positive immune pressure on tumor cells. The development of anti-CTLA4, anti-PD-1, and anti-PDL1 monoclonal antibodies that elicit antitumor clinical responses in a variety of solid cancers has solicited the inclusion of these immunotherapies in cancer treatment, and several of these antibodies are approved for cancer treatment (pembrolizumab, ipilimumab, nivolumab, etc.) [88].

Metabolic reprogramming of tumor cells can create a hostile TME for antitumor immune cells through glucose and amino acid depletion, hypoxia, high acidity through extracellular lactate release, etc., thereby reducing their activation and proliferation. Various metabolic nodes can be targeted for restoration of effective immune response to tumor cells that include regulation of aerobic metabolism [glucose transporter (GLUT), PI3K inhibitors], inhibition of lactate production [lactate dehydrogenase (LDH) inhibitors], etc. [89]. Additionally, novel metabolic targets such as indoleamine 2,3-dioxygenase-1 (IDO1) that degrade tryptophan to kynurenine, an immunosuppressing metabolite that acts as immune breaks, are being used in immunotherapy [90].

3.5 Cancer Invasion and Metastasis

Tumor spread from the primary site of origin to secondary sites of colonization, commonly referred to as invasion and metastasis, is a widely manifested clinical problem and one of the major hallmarks of cancer. This process is executed as a cascade of events, with each event being characterized by specific molecular changes in the tumor cells and TME. The major processes in malignancy are invasion, intravasation, extravasation, and colonization of a secondary metastatic niche. Invasion is characterized by the loss of cell–cell adhesion capacity (epithelial-to-mesenchymal transformation or EMT), maintained by epithelial cellular junctions (tight junctions, adherens junctions, gap junctions, desmosomes, and integrins), and alterations of the tumor cell–basement matrix. The major features of an EMT include loss of epithelial markers, such as E-cadherin, α-catenin, claudins, occludin, and zonula occludens-1 (ZO-1), an increased expression of mesenchymal markers, such as N-cadherin, vimentin, and fibronectin, and a reorganization of the cytoskeleton [e.g., loss of epithelial protein lost in neoplasm (EPLIN)] [91, 92]. EMT-inducing signals are initiated by growth factors—hepatocyte growth factor (HGF), epidermal growth factor (EGF), and transforming growth factor-β (TGF-β)—that, in turn, induce downstream activation of EMT transcription factors that include Snail, Slug, Twist, and zinc-finger E-box binding homeobox 1 (ZEB1) as well as activation of matrix metalloproteinases (MMPs) that degrade a variety of basement matrices [92, 93]. EMT-inducing transcription factors and inflammatory cytokines such as nuclear factor kappa B (NF-κB), IL-4, CCL5, etc. guide most of the steps in the invasion–metastasis cascade [94]. Finally, the seeding of circulating tumor cells into a secondary site is facilitated by a supportive stroma that arises in a primary tumor and a permissive TME composed of stromal support cells at the metastatic site such as the stromal-derived factor 1 (SDF1)–CXC motif chemokine receptor 4 (CXCR4) chemokine axis [94]. Metastasis is thus a highly complex process regulated through oncogenes and tumor suppressors, genomic instability, inflammatory cytokines, proangiogenic factors, transcription, metabolic alterations (hypoxia, pH, etc.), and tumor stromal interactions that promote the establishment of tumor cells at secondary sites [95]. Targeting metastasis is thus a challenging task, and the therapeutic aim should be prevention of an initial/additional metastasis in high-risk patients and shrinkage of established lesions. This would involve a multimodal treatment approach comprising a combination of distinct drug class molecules, with regular monitoring for minimal residual disease. Given the challenges in designing an appropriate treatment strategy, metastasis seems an extremely tough condition to deal with. Targeting metastasis with denosumab, a monoclonal antibody that blocks the receptor activator of the NF-κB ligand (RANKL), has shown clinical benefit in solid tumor patients with bone metastases. Denosumab is FDA-approved for prevention of skeletal-related events (SREs) in solid tumors and as an adjuvant therapy in prostate cancer [96, 97]. Other prospective drug development programs targeting metastasis include Bevacizumab (anti-VEGF), Cilengitide (αvβ3 and αvβ5 integrin peptide inhibitor) and SRC/Bcr-Abl dual-kinase inhibitors dasatinib and saracatinib [97].

4 Conclusions

Translational oncology research in the areas of oncogene addiction, tumor suppression, cell cycle regulation, immune tumor cell interaction, and metabolic reprogramming of the TME has led to the emergence of an arsenal of drugs for treating cancers in the last few decades. These key areas continue to hold a huge potential for addressing unmet medical needs and therapeutic progress in the practice of oncology.

1 Introduction

Surgical oncology (also called oncological surgery) is a surgical specialty dealing with the surgical management of cancerous and tumorous conditions. It is one of the oldest, curative modalities of cancer therapy. Oncological surgery is now recognized as a specialized and advanced field of surgery that requires dedicated training and practice. Significant changes in oncological surgery have occurred in recent decades. The two broad changes in oncological surgery have been the incorporation of surgery as part of the treatment algorithm with other modalities of treatment (rather than the only form of treatment) for solid tumors and the need to super-specialize in various subspecialties within this vast field like head and neck oncology, breast oncology, gynecological oncology, thoracic oncology, gastrointestinal oncosurgery, musculoskeletal oncology, etc. Oncological surgery encompasses guiding principles, improved perioperative care, minimally invasive techniques, and a special emphasis on expedited recovery principles. There has also been a shift toward the increased use of conservative and minimally invasive surgery with an aim to decrease morbidity without compromising disease outcomes.

Oncological surgery is a vast topic, and its complete description is beyond the purview of a single chapter. This chapter aims to outline the fundamentals and guiding principles of oncological surgery in the management of solid tumors.

2 Historical Perspective

- Earliest description of surgical extirpation of tumors: Edwin Smith papyrus from the Egyptian Middle Kingdom (circa 1600 BC)
- McDowell: First elective surgery for visceral tumors in 1809
- John Collins Warren: Submandibular gland excision in 1846 under general anesthesia
- Other important milestones have been depicted in Table 1.

Table 1 Major milestones in the field of oncological surgery

Year	Name	Contribution
1867	Joseph Lister	Introduction of antisepsis
1860–1890	Albert Theodore Billroth	First gastrectomy, laryngectomy, esophagectomy
1878	Richard von Volkmann	Excision of cancerous rectum
1880s	Theodore Kocher	Development of thyroid surgery
1890	William Halsted	Radical mastectomy
1896	G. T. Beatson	Oophorectomy for breast cancer
1904	Hugh H. Young	Radical prostatectomy
1906	Ernest Wertheim	Radical hysterectomy
1908	W. Ernest Miles	Abdominoperineal resection for rectal cancer
1912	E. Martin	Cordotomy for the treatment of pain
1910–1930	Harvey Cushing	Development of surgery for brain tumors
1913	Franz Torek	Successful resection of cancer of the thoracic esophagus
1927	G. Divis	Successful resection of pulmonary metastases
1933	Evarts Graham	Pneumonectomy
1935	A. O. Whipple	Pancreaticoduodenectomy (Whipple's surgery)
1945	Charles B. Huggins	Adrenalectomy for prostate cancer
1958	Bernard fisher	Organization of the National Surgical Adjuvant Breast and Bowel Project (NSABP) to conduct prospective randomized trials

3 Operative Risk Assessment

Operative risk is a combination of operative mortality and major morbidity. “Operative mortality” is usually defined as mortality occurring within 30 days of any surgical procedure. Morbidity and complications of surgery are now well-documented for most oncological procedures. Numerous classification systems are available for classifying the grades of complications, and most solid tumor surgeries have specific validated instruments for each subsite. Examples include the ISGPS (International Study Group of Pancreatic Surgery) definition and grading of postoperative pancreatic fistula [2] or the ECCG (Esophagectomy Complications Consensus Group) definition and grading of anastomotic leak [3] (Table 2). However, the most commonly used system to grade complications is the Clavien–Dindo classification of surgical morbidity [4–6] (Table 3). This classification has been validated across many oncological solid tumor surgeries [7–9].

An understanding of the expected complication rates and associated morbidity and mortality from surgeries being performed for cancers is vital in preoperative counseling and decision-making to choose the correct treatment options for patients. Unlike non-oncological surgery, the balance between disease outcomes and morbidity of surgery has to be titrated prior to embarking on extensive procedures.

3.1 Preoperative Fitness Assessment and Operative Risk Prediction

Operative risk assessment involves many components of care such as patient-related factors, performance status, surgical factors, anesthetic techniques, etc.

The American Society of Anesthesiologists (ASA) has developed a classification/grading of the physical fitness of patients undergoing surgery [10, 11]. This is the commonest and most robust form of assessment to evaluate physical fitness for surgery. Patients are grouped as ASA 1–5 (Table 4).

There are numerous operative risk stratification systems, which have been validated for solid tumor surgery. The POSSUM (Physiology and Operative Severity Score for the enUmeration of Mortality and morbidity) risk stratification

Table 3 Clavien–Dindo grading of postoperative complications

Grade	Description
Grade I	Any deviation from the normal postoperative course with no need for pharmacological, radiological, surgical, or endoscopic interventions Drugs that can be used: antiemetics, antipyretics, analgesics, diuretics, and electrolytes Also includes wounds that have been opened bedside for drainage
Grade II	Use of drugs (other than those listed under grade I), parenteral nutrition, and blood and blood products
Grade IIIa	Requires surgical/endoscopic/radiological intervention not under general anesthesia (GA)
Grade IIIb	Requires surgical/endoscopic/radiological intervention under GA
Grade IVa	Life-threatening complication needing intensive care unit (ICU) care with single organ dysfunction (includes dialysis)
Grade IVb	Life-threatening complication needing ICU care with multiple organ dysfunction
Grade V	Death of the patient
Suffix “d”	Added to indicate “disability” when the patient suffers from any of the above complications at the time of discharge

GA general anesthesia

Table 4 ASA grading of risk

Class	Description
I	Patient is completely healthy and fit
II	Patient has mild systemic disease
III	Patient has severe systemic disease that is not incapacitating
IV	Patient has incapacitating disease that is a constant threat to life
V	A moribund patient who is not expected to live 24 h with or without surgery
E	Emergency surgery. E is placed after the Roman numeral

From Ref. [11]

Table 2 Definition and grading of complications

Group	Definition	Grades	
ISGPS	Drain output of any measurable volume with an amylase level more than three times the upper limit of institutional normal serum amylase associated with a clinically relevant condition directly related to the postoperative pancreatic fistula	A B C	Biochemical leak, no clinical outcomes Change in the postoperative management: drains either left in place >3 weeks or repositioned through endoscopic or percutaneous procedures Requiring re-surgery or leading to single or multi-organ failure and/or mortality
ECCG	Full thickness defect involving the esophagus, anastomosis, staple line, or conduit irrespective of the presentation or method of identification	I II III	Local defect requiring no change in therapy, treated medically, or treated with dietary modification Localized defect requiring interventional but not surgical therapy Localized defect requiring surgical therapy

system was described for patients undergoing surgical procedures. This score has been validated in many solid tumor surgeries and has shown a good predictive value for postoperative morbidity and mortality [12–14].

Most of the scoring systems for morbidity or mortality use a combination of the following criteria.

- *Age of the patient*: Increasing age is directly proportional to the risk of postoperative complications. The risk of postoperative mortality is 30–35 times higher in patients aged more than 70 years of age compared to their younger counterparts.
- *Comorbidities*: As the number of comorbidities increase (also related to the increasing age of the patient), the risk of morbidity and mortality increases. For example, diabetic patients run the risk of infections, dyselectrolytemias, and gastroparesis.
- *Poor nutritional status*: Albumin levels correlate directly with postoperative outcomes, especially for major gastrointestinal surgeries. Low albumin levels result in poor wound healing and increase the risk of anastomotic leaks.
- *Cancer cachexia*: This is an extreme form of malnutrition characterized by weight loss and sarcopenia seen in advanced cancers and contributes to poor outcomes after palliative surgeries in such patients [15].
- *Addictions*: Smoking increases the risk of postoperative mortality by 1.5–4-fold. It impairs wound healing and affects ciliary epithelium functioning, resulting in infections and respiratory infections.
- *Multiple prior surgeries*: These increase the risk of morbidity postoperatively.
- *Prior chemotherapy/radiotherapy*: Many patients with cancer undergoing surgery would be exposed to chemotherapy or radiotherapy prior to surgery. Chemotherapy increases the risk of postoperative infections (as total leukocyte counts fall), whereas radiotherapy increases the risk of infections and wound complications.
- *Increased body mass index (BMI)*: Obese patients with a high body mass index (BMI) are susceptible to pulmonary complications, thromboembolism, and delayed wound healing postoperatively with a 1–1.7 times higher risk of mortality [16].
- *Coagulopathies*: These include thrombocytopenia/hypercoagulable states resulting from cancer per se or part of the treatment increases the risk of postoperative morbidity and mortality by two- to threefold.

4 Diagnostic Biopsy in Solid Cancers

A diagnostic biopsy is used in a number of solid cancers. It is important to note that in most solid tumors, a diagnosis of cancer can be readily obtained by less invasive procedures like fine needle aspiration cytology (FNAC), which can be either clinician-performed or image-guided. Open biopsies are rarely recommended for diagnosis of solid tumors.

4.1 Types of Biopsies Performed

- *Open excision biopsy*: This is a type of biopsy, where the lesion or the node is excised in toto for obtaining a diagnosis (e.g., for better characterization of suspected metastatic lymph nodes that are inconclusive on FNAC), or excision biopsy of oral leukoplakias for obtaining histopathological diagnosis.
- *Tru-cut or core biopsy*: This is a biopsy, where a small core of tissue is removed from larger masses, using special needles (like the J needle or Jamshidi needle for bone biopsies) to help characterize the tumors better (e.g., core biopsy of breast cancers to perform immunohistochemistry for biomarkers [estrogen receptor (ER)/progesterone receptor (PR)/human epidermal growth factor receptor 2 (HER2)-neu) for therapy]. These biopsies may be performed with image guidance in cases of inaccessible tumors.
- *Endoscopic biopsy*: These biopsies are performed for tumors within luminal organs (e.g., colonoscopic biopsy for colonic cancers).

4.2 Principles of Performing Biopsies in Solid Tumors

- Avoid an open biopsy whenever feasible.
- Use noninvasive techniques of obtaining diagnosis like an FNAC, prior to deciding to perform a biopsy.
- If the FNAC is inconclusive or better characterization of tumors is required, then perform a biopsy.
- Discrete lymph nodes in accessible locations are best removed as a complete node.
- Perform a core biopsy for larger masses.
- Use image guidance [ultrasonogram (USG)/computed tomography (CT) scanning] when biopsies are to be performed from inaccessible locations or if masses are close to critical anatomical structures like major blood vessels, trachea, etc.
- Plan incisions of biopsies in a way that these incisions can be excised within the scar of the proposed surgery.

5 The Role of Surgery

5.1 Preventive/Prophylactic Surgery

Preventive or prophylactic surgery is defined as the preemptive operative removal of an organ prior to malignant transformation or when the cancer is still in situ. It generally involves removal of the organ at risk so that future cancer can

Table 5 Prophylactic cancer surgeries

Condition	Cancer	Prophylactic surgery
Cryptorchidism	Testicular	Orchiopexy
Adenomatous polyposis coli	Colon	Total colectomy
Familial colon cancer	Colon	Colectomy
Ulcerative colitis	Colon	Colectomy
MEN syndrome 2	Thyroid (medullary)	Total thyroidectomy
Familial breast cancer	Breast	Mastectomy
Familial ovarian cancer	Ovary	Salpingo-oophorectomy
Hereditary diffuse gastric cancer	Diffuse gastric cancer	Total gastrectomy
Lynch syndrome	Endometrium Colon	Hysterectomy and colectomy

Modified from [1]

be prevented. Most prophylactic surgeries for malignancy are conducted because of the presence of a genetic mutation that has a high penetrance and is a known cause of the particular malignancy. Prophylactic surgeries and conditions are listed in Table 5.

5.2 Criteria for Prophylactic Surgery

- The genetic mutation involved in the disease process must have high penetrance.
- A highly reliable test to identify patients with these mutations should be present.
- The organ being removed must be associated with low morbidity.
- There should be a suitable replacement of the function of the organ being removed.
- A reliable method to determine whether that patient has been cured over time should be available.

5.3 Examples of Prophylactic Surgery

- MEN (multiple endocrine neoplasia) syndrome [17, 18], which includes MEN-1, MEN-2A, and MEN-2B, characterized by two or more endocrine tumors with an autosomal dominant pattern of inheritance. Patients with MEN-2 mutations have an increased risk of medullary thyroid cancers warranting prophylactic total thyroidectomy in these patients at an early age.
- Mutations of the breast cancer susceptibility genes (BRCA 1 and BRCA 2) are associated with the hereditary breast and ovarian cancer syndrome (HBOC) characterized by an increased risk of breast and ovarian cancers in affected individuals [19, 20] which may warrant prophylactic mastectomy and/or salpingo-oophorectomy.
- FAP (familial adenomatous polyposis) syndrome is characterized by hundreds to thousands of polyps carpeting the entire colon and often the rectum. The gene responsible is the APC gene on chromosome 5q21. These patients have an increased risk of colon cancer, thus warranting total colectomy at an early age, and also an increased risk of periampullary cancers, desmoids, and central nervous system (CNS) tumors [21].

6 Curative Surgery

Surgical extirpation of the tumor and the affected nodal basins remains the most effective method to cure patients with organ-confined solid cancers. Oncological surgery involves the removal of the primary tumor with gross and microscopic, pathologically negative margins along with removal of the draining lymph nodes.

6.1 Principles of Resection of the Primary Cancer

Research on the outcomes and factors predicting recurrence and survival in oncological surgery has made it possible to have guidelines for the extent of resection of primary tumors, for every subsite. The definition for adequate margins, need for prophylactic nodal dissections, extent of nodal dissection, and reconstructive procedures vary significantly across every tumor subtype. A knowledge and understanding of all of the above factors is required prior to embarking on any oncological surgery. Describing principles of resection for every subsite of cancer is beyond the scope of this chapter. Highlighted below are certain important basic surgical principles of oncological surgery.

- The primary tumor is to be excised in entirety, including the adjacent normal tissues as margins, to account for microscopic spread of the disease. All efforts to achieve pathologically adequate, cancer-free margins are a prerogative of any oncological surgery.
- The margins that are considered adequate have been defined for most solid tumors, and the surgeon should have a priori knowledge of what constitutes a negative margin before embarking on surgery for a particular cancer.
- Spillage, rupture, contamination, and excessive handling of the primary cancer are best avoided.
- During resection, all attempts should be made to spare important anatomical structures without compromising the margins of resection.
- Minimally invasive techniques of surgery should be used in indications where their use has shown to decrease post-

operative morbidity, without impacting disease outcomes. This is the most important in pelvic surgeries like prostatectomies, hysterectomies, and rectal cancer resections.

- The extent of surgical resection is categorized as:
  - R0: Complete removal of the tumor, with no gross or microscopic residual disease
  - R1: Complete removal of the tumor with the presence of microscopic residual disease
  - R2: Incomplete tumor removal with the presence of gross macroscopic residual disease

The importance of categorizing every oncological surgery as R0, R1, or R2 stems from the fact that in most solid cancers, completeness of resection is among the most important prognostic factor to predict both recurrence and survival. Patients undergoing R1 resections generally need adjuvant therapy to sterilize the margins in order to avoid local recurrences. Those undergoing R2 resections have poor oncological outcomes with survival rates similar to those who have not undergone resections, e.g., pancreatic cancer patients who undergo R2 resections show poor survival rates in comparison to those undergoing R0 resections [22–24]. In certain tumors like ovarian cancer, tumor debulking and leaving back minimal residual disease followed by adjuvant chemotherapy have been shown to have acceptable results [25]. However, in most other cancers, surgery should be deferred if the clinical examination and radiological imaging suggest a high probability of R2 resections.

6.2 Minimally Invasive Surgery in Oncology

Minimally invasive surgery is slowly and steadily making its foray into oncology. Any oncological procedure may be performed using the principles of minimally invasive surgery. Minimally invasive surgery can be performed by two methods, namely, laparoscopic or robotic, depending on the availability of expertise and equipment. Both methods combine the benefit of potential oncological safety with the advantages of lesser postoperative pain, early discharge from the hospital (reduced hospital stay), and smaller incisions. However, they come at the expense of increased operative cost and time, need for specialized training, and expertise to perform the procedure. Minimally invasive surgery should be performed in indications where there is a proven benefit of these procedures either in decreasing postoperative morbidity and hospital stay or improving quality of life. Cancers of the colorectum, esophagus, and stomach are increasingly being performed using minimally invasive approaches with equivalent oncological outcomes as traditional open surgeries [26].

6.3 Resection of Metastatic Disease

Common sites of metastases from solid tumors include the lungs, liver, and bone. In most cancers, the presence of distant metastases to these organs portends an extremely poor prognosis for patients. Resection of metastatic disease is generally performed for two indications

1. To improve oncological outcomes by resection of the metastases, e.g., resection of pulmonary metastases in soft tissue sarcomas has shown to improve survival. In a study by Belal et al. [27], the 5-year overall and disease-free survival of patients undergoing metastasectomy was 24% and 21%, respectively, indicating that such patients had improved survival outcomes. Similarly, resection of hepatic metastases in colorectal cancers has shown improvement in survival ranging from 35 to 60% [28–30].
2. To relieve symptoms caused by metastatic disease, e.g., resection of metastases causing impending fractures, in weight-bearing bones like the femur, tibia, etc. and decompression and fixation of spinal metastases causing neurological impairment. Life-threatening brain metastases from cancers like thyroid cancers can also be undertaken.

The general principles of resection of metastatic disease include [31]

- Resection has better results for oligometastases rather than for multiple metastases.
- A complete resection of the metastases should be deemed feasible prior to embarking on surgery.
- The primary cancer should be controlled or easily controllable at the time of metastasectomy.
- Disease-free interval (DFI) plays an important role in determining outcomes after a metastasectomy. The longer the DFI, the better are the outcomes of metastasectomy.
- There are better outcomes for metachronous rather than synchronous presentation.
- Patient- and tumor-related factors should be taken into consideration prior to deciding on a metastasectomy.
- Metastasectomy is best avoided in patients who have aggressive malignancies, multiple metastases, a poor DFI, and multiple comorbidities.

7 Reconstructive Surgery in Oncology

After oncological resections, restoring cosmesis and function remains a tremendous challenge. This is especially so for surgeries involving head and neck and breast cancers.

Functional rehabilitation after ablative surgery for the oral cavity and laryngopharynx is a big challenge. With improvements in microvascular surgery and prosthetic implants, reconstruction of complex defects is now feasible.

7.1 Principles of Reconstructive Surgery [32]

- Preoperative planning along with estimation of functional and cosmetic deficits is mandatory.
- As far as possible, “like tissues to be replaced with like,” e.g., reconstruction after mandibular resection should be done using a bone flap rather than just a muscle-based flap.
- Reconstruction of all components of excision should be attempted.

8 Palliative Surgery

- Used for pain relief or restoration of function
- Can improve quality of life in these patients with advanced cancers
- Certain examples include (1) palliative bypass in case of intestinal obstruction; (2) toilet mastectomy for removing fungating/bleeding breast cancers; and (3) removal of masses causing intractable pain.
- Usually associated with high morbidity and mortality in view of advanced cancer and poor performance status of patients.

1 The Discipline of Radiation Oncology

Radiation oncology is a specialized medical discipline that deals with expertise in the use of therapeutic ionizing radiation for the treatment of both benign and malignant conditions. The therapeutic effect of ionizing radiation stems from a close interaction of multiple factors like the physical properties of radiation, the biology of tumor and normal tissues, host immunogenic response, heat, oxygen, and other therapies like chemotherapy and surgery. The therapeutic goal of radiation oncology is to achieve maximum tumor cell kill while sparing the normal tissue of radiation damage, thereby widening the therapeutic ratio. Therapeutic radiation can be delivered either from a radiation source placed away from the target tissue, i.e., external beam radiotherapy/teletherapy, or from a radiation source placed into or extremely close to the target tissue, i.e., brachytherapy. Radiation in teletherapy could be derived from either the

spontaneous disintegration of a radioactive source like cobalt-60 (γ-rays) or artificially produced using linear accelerators (X-rays). Based on the way that the radiation source is placed in proximity to the target tissue, the technique of brachytherapy may be classified into five broad categories as enumerated in Table 1. Based on the rate at which the radiation dose is delivered, brachytherapy may be classified as a high dose rate (HDR) >12 Gy/h, a medium dose rate (MDR) 2–12 Gy/h, and a low dose rate (LDR) <2 Gy/h A typical prescription for radiotherapy treatment would include information on the total dose, the number of fractions of radiation, the dose per fraction, and the total duration of the treatment. The clinically relevant unit while reporting the dose of radiation is Gray (Gy). One Gray is defined as the absorption of one joule of energy per kilogram of matter. The SI (International System of Units) unit is J/kg^{-1}. Multiple factors like tumor biology, tolerance of the normal tissue, type of radiation used, and concurrent therapy along with radiation play a role when deciding the prescription dose for a particular tumor.

2 The Historical Aspects of Radiation Oncology

The history of therapeutic radiation dates back to 1895, when Wilhelm Conrad Roentgen discovered X-rays, which was immediately followed by the discovery of radioactivity by Marie Curie in 1898. Radium-226 was the first radioactive isotope to be used for medical treatment, but it fell out of favor due to potential hazards like leakage of the gaseous daughter radioactive product, radiation exposure to personnel (preloaded), dosimetric inconsistencies due to construction, etc. Cobalt-60 was used as an alternative to radium-226 in the 1950s [1]. Cobalt teletherapy units were used for many years before being gradually phased out in favor of the more versatile linear accelerators. In many institutions across India, cobalt-60 teletherapy machines still remain the workhorse due to their lower cost, simplicity of use, and low maintenance features compared to those of the more complex linear accelerators. The first linear accelerator with 8-MV photons was installed at the Hammersmith Hospital in London in 1952. The principal advantage of the initial linear accelerators was the higher energy of photons and the possibility to have beams of multiple energies. These accelerators did not have in-built beam-shaping devices. In 1968, Japanese scientists showed that it was possible to shape beams with the use of multileaf collimators (MLCs), thus producing a more conformal treatment field [2]. In 1978, automated computer-controlled linear accelerators were developed [3]; these are the cornerstone of radiotherapy today. The roots of image guidance for cobalt teletherapy units during radiation therapy to confirm the location of the target can be traced back to 1960 in London, and, later in 1985, it was incorporated into the modern linear accelerators [4]. In 1999, more refined image-guided feedback systems were developed [5]. The basic concept of intensity modulation has been used since 1959 [6], with the use of compensators and beam modifiers. It was in the 1980s and 1990s that computing technology developed significantly, leading to the development of modern intensity-modulated radiation therapy (IMRT) [7]. An exciting advancement in IMRT/image-guided radiotherapy (IGRT) was achieved in 1993, when TomoTherapy was developed by Mackie [8]. The proton was discovered in 1917 by Ernest Rutherford; in 1930, Ernest O. Lawrence developed the cyclotron to accelerate these protons for medical treatment. In 1954, the first patient with pituitary adenoma was treated with protons at the University of California, Berkeley, but the first hospital-based proton center was developed in 1990 in Loma Linda, California. Since its early inception, proton therapy has also evolved and now has much robust planning like intensity-modulated proton therapy (IMPT) [9]. In India, the history of radiation oncology started with the installation of the radium institutes in Patna, Agra, Madras, and Lahore. The first telecobalt machine was installed at the Adyar Cancer Institute in 1956 [10]. The first linear accelerator was installed in 1976 at the Adyar Cancer Institute [11]. According to the International Atomic Energy Agency-Directory of Radiotherapy Centres (IAEA-DIRAC), there are currently 352 radiotherapy centers in India with 264 linear accelerators [12].

3 The Biological Basis of Radiotherapy

3.1 Direct and Indirect Effects of Radiation

Radiotherapy affects tumor cells by the deposition of high physical energy of radiation in the irradiated medium [13]. When a photon enters the body, it can either pass through without any interaction or it can be completely absorbed or scattered based on the entry. The various types of interactions of photons with matter are presented in Table 2. The main target of damage in an irradiated cell is the DNA [14]. The physical interaction of radiation with the molecular structure of the cell lasts for only 10–30 seconds. The deposited energy can cause DNA damage in two ways—by direct and indirect mechanisms. In the direct mechanism, the incident radiation leads to the release of high-velocity electrons and secondary photons, thus causing direct damage to the DNA strands. In the indirect mechanism, the incident radia-

Table 2 Types of interactions of photons with matter [17]

Type of interaction	Energy range in water	Phenomenon
Photoelectric effect	Up to 25 keV	Interaction with the outer-shell electrons. Complete transfer of energy to the outer-shell electron, which leads to ejection of the electron from the orbit
Compton scattering	10–150 keV	Interaction with the inner-shell electrons. Absorption of a part of the energy, which leads to scattering of the photon and also expulsion of the electron
Pair production	>1.02 MeV	Interaction with the nucleus. The photon interacts with the nucleus to produce an electron and a positively charged positron

tion interacts with the water content of the cell, which constitutes up to 70–80%. This leads to the production of reactive oxygen species and free radicals, which contain an unpaired electron that makes them reactive. The majority of the effects due to radiation are caused by the indirect mechanism [15]. The number of free radicals produced by the ionizing radiation is a function of the dose [16].

3.2 Cellular Targets of Radiation

The main cellular target of radiation is the DNA. The damage caused by radiation on DNA can be of many types, such as double-strand breaks (DSBs), single-strand breaks (SSBs), protein DNA cross-linking, and multiple combinations. In DSBs, both the DNA strands are broken, whereas in SSBs, only one strand is broken. Based on the type of radiation, the numbers of DSBs and SSBs vary. When a cell is damaged by radiation, it reacts by arresting the progress in its cell cycle, activating apoptosis, or DNA repair. The major cell cycle checkpoints are the G1–S phase by the retinoblastoma (RB) gene, S phase, and G2 checkpoints. Based on the phase of the cell cycle, the process of repair starts. The two main methods of DSB repair are the homologous repair and the non-homologous end-joining repair. The choice for the type of repair depends on the position of the cell in the cell cycle. For homologous repair, there must be a template strand of DNA that is available only in the S and G2 phases. Thus, homologous repair predominates in the S phase. Homologous repair is the most accurate for repair, thus conferring radioresistance to the cells in the S phase. However, non-homologous end-joining repair is non-cell cycle-specific and is seen in all phases. Other forms of repair include base excision repair, mismatch repair, and nucleotide excision repair. If the cell is able to repair the DNA damage, then it progresses through the cell cycle. If not, then the process of apoptosis sets in, leading to apoptosis of the cell, which is known as interphase death. Apoptosis is mediated by the p53 gene. Some cells progress along the cell cycle but undergo death when trying to replicate by mitosis due to chromosomal aberrations. This is called mitotic death. Most of the cell deaths due to radiation occur as a result of mitotic catastrophe rather than the initial effect itself. A unique phenomenon seen in some cells is the bystander effect. This is cell death occurring in cells due to irradiation of the neighboring cells. This phenomenon can be explained by the secretion of certain toxic substances by the dying cells into the media or by the presence of gap junctions, which can facilitate the transfer of reactive oxygen species between cells. DNA damage can be classified based on the repair capacity. Lethal damage is that which cannot be repaired; potential lethal damage refers to that which can become lethal under suboptimal conditions but can be repaired under suitable conditions. Sublethal damage is that which can be usually repaired under normal conditions, but multiple sublethal damages may interact to form lethal damage.

3.3 Factors Influencing the Radiation Effect on Cells

The effect of radiation on a cell is governed by the 5Rs of radiobiology: repair, reassortment, repopulation, reoxygenation, and radiosensitivity. Repair, as described previously, can be either homologous or non-homologous end-joining repair. Reassortment is a result of the halt in the cell cycle phase due to activation of checkpoints. Thus, when a tissue is irradiated, some cells may be in the radioresistant S phase or in the radiosensitive G2–M phase, thus leading to only partial cell kill. However, after repair of the cells in the radioresistant phase, they progress to the radiosensitive G2 phase. Thus, delivery of a second fraction of radiation during this time will lead to death of the remaining cell clones. This forms the basis of fractionation. Repopulation is due to rapid growth of the cell clones that have survived the initial phase of radiation. This confers radioresistance during radiotherapy, and an additional dose is required to control these rapidly proliferating cells. Oxygen provides free radicals that are vital for the fixation of DNA damage. The relation between the 5Rs of radiobiology and the hallmarks of cancer are provided in Table 3.

The type of ionizing radiation also plays an important role. A radiation incident on a medium can be classified based on the amount of energy deposited in the medium. Linear energy transfer (LET) is defined as the average energy (in kiloelectron volts) given up by a charged particle traversing a distance of 1 μm. High LET radiations produce more ionizations per unit track. Examples of high LET radiations include neutrons, carbon ions, and alpha particles. Examples of low LET radiations include megavoltage photons, electrons, and cobalt-60 γ-rays. Another parameter used to describe the efficiency of radiation is the relative biological effectiveness (RBE). RBE is the ratio of the dose

Table 3 Correlation of the 5Rs of radiobiology with the hallmarks of cancer [18]

5Rs of radiobiology	Hallmarks of cancer
Repair	Growth factor self-sufficiency, evasion of apoptosis
Repopulation	Growth factor self-sufficiency, insensitivity to anti-growth factor signals, telomerase activation
Redistribution	Growth factor self-sufficiency, insensitivity to the anti-growth factor
Reoxygenation	Angiogenesis, growth factor self-sufficiency
Radiosensitivity	Growth factor self-sufficiency, evasion of apoptosis, insensitivity to anti-growth factor signals

of the reference radiation to that of the test radiation to produce the same biological effect. The reference radiation is usually 250 kVp X-rays or Co-60 rays. RBE is in the range of 2–10 for high RBE radiations. As LET increases, RBE also increases till it reaches 100 keV/mm. After this, the overkill effect sets in, which leads to wastage of the excess energy. Oxygen, as described above, is important for fixing DNA damage and is also a source of free radicals. Hence, the effect of oxygen can be determined by the oxygen enhancement ratio (OER). The OER is defined as the ratio of dose in hypoxia to that in air. The OER for X-rays is 3. There is a steep rise in the OER from 0.5 to 20 mmHg of oxygen followed by a plateau and a modest increase only. The opposite situation is when tumor hypoxia predominates. This leads to a rapid increase in radioresistance. Tumor hypoxia can be of two types, namely, acute and chronic. Acute hypoxia is due to the clogging of the blood vessels by tumor/blood cells or temporary collapse of the blood vessels. Chronic hypoxia is due the tumor outgrowing the vascular capacity of the feeder vessel. Thus, hypoxia can considerably increase tumor resistance to radiotherapy due to lack of oxygen and can also reduce the bioavailability of systemic drugs in the tumor due to poor vascular supply. The body's immune response also plays an important role in radiotherapy. Radiation upregulates antigen expression and cytokine release, thus mimicking a state of inflammation. This activates the antigen-presenting cells and sensitization of the T cells. This can lead to immune activation and control of distant metastatic tumor deposits. This effect is called the abscopal effect. With the advancements in immunotherapy, this is an upcoming frontier for research. The effect of radiotherapy can be potentiated with the use of systemic radiosensitizers like cisplatin and 5-fluorouracil. The role of cisplatin as a radiosensitizer is well-demonstrated in malignancies of the head, neck, and cervix. The main mechanism of radiosensitization is the formation of inter- and intra-strand adducts and the inhibition of DNA repair. The physical and biological properties of heat can be used to potentiate the effect of radiation. Temperatures from 39.5 to 43 °C have been used clinically. Hyperthermia coagulates and denaturizes the necessary proteins required for DNA repair. It also induces heat shock proteins (HSP-70), which upregulate the immune response. It has also been seen to cluster DNA damage so that the DSB changes increase [19, 20].

3.4 The Acute and Late Effects of Radiation

Radiobiology of the adverse effects following radiotherapy is critical for identification and appropriate management. Acute events are defined as effects that are seen within 90 days of starting radiotherapy; this is typically seen in skin and mucosal layers. Those beyond 90 days are termed as "late effects." The pathogenesis of acute events is a cascade of events following the start of radiotherapy. Irradiation of a normal tissue leads to vascular effects and inflammation; this, in turn, upregulates the functional stem cells in the basal layers. However, due to exposure to radiation, there is a destruction of these stem cells, which leads to hypoplasia and inadequate healing of the affected region. Inadequate healing may be complicated by a secondary infection. The reduced turnover of the functional cells is the primary cause of acute reactions, and, hence, the onset of the reaction typically correlates with the loss of residual functional cells and cell turnover of the affected region, e.g., 9 days after fractionated radiation to the mucosa [21]. The severity of acute reactions is based on the total dose of radiation, the duration of radiation, fractionation, and use of concurrent therapy. Late effects due to radiation are due to a complex interplay between the immune cells, fibroblasts, and vasculature. These are initiated with the loss of functional cells, which leads to compensatory proliferation of structural supporting cells such as fibroblasts. Radiation causes apoptosis of the endothelial cells, loss of smooth muscle, and damage to the surrounding veins and capillaries. Sclerosis and end arteritis occur in the arterioles, which may compromise blood supply. This causes proliferation of the defective vasculature, which lacks a precapillary sphincter, and is telangiectatic. This is prone to bleeding. Irradiation also causes differentiation of fibroblasts into fibrocytes with an increase in the production of transforming growth factor-β. This leads to additional fibrosis and collagen synthesis. The late effects are inversely dependent on the dose per fraction. Consequential reactions are the conversion of acute reactions into late reactions due to severity. This is typically seen in the skin and mucosa. An important concept in understanding the effect of radiation on a normal tissue is the functional arrangement of the irradiated organ. Each organ is made up of a functional subunit (FSU), and the arrangement is of prime importance while planning radiotherapy. Parallel organs are those that have their FSUs arranged in a parallel manner, whereas serial organs are those with FSUs arranged serially. This arrangement is not mutually exclusive of each other, but there is a degree of relativism between them. Relatively serial organs such as the spinal cord are sensitive to the maximum dose, whereas relatively parallel organs like the liver are sensitive to the mean dose. Mixed organs like the lungs, where the tracheobronchial tree is arranged serially and the parenchyma is arranged in a parallel manner, are sensitive to both the mean and maximum doses.

3.5 Fractionation

The intention behind fractionation is to reduce the number of hypoxic cells through reoxygenation, reduce the cells in the radioresistant phase by redistribution, improve oxygenation, and reduce hypoxia by opening of the blood vessels or shrinkage of the tumor. Fractionation also utilizes the recovery of the normal tissue between fractions, hence reducing reaction changes. The different types of fractionations are provided in Table 4. The main aim of modulating the dose per fraction and frequency is to widen the therapeutic window. While comparing different fractionation schedules, it is important to deliver the same biologically equivalent dose. Biologically equivalent dose (BED) = $nd\ [1 + d/(\alpha/\beta)]$. The BED must be calculated for acute- and late-reacting tissues when changing fractionation. The final dose must be reported in the equivalent dose in 2-Gy fractions (EQD2) (conventional). EQD2 = $nd\ [d + (\alpha/\beta)/2 + (\alpha/\beta)]$, where n is the number of fractions, d is the dose per fraction, and α/β is the dose where the linear cell kill is equal to the quadratic cell kill. The assumed α/β for acute- and late-reacting tissues are 10 and 3, respectively. The radiobiological basis of altered fractionation is provided in Table 5.

Table 4 Types of altered fractionations

Fractionation type	Dose per fraction (Gy)	No. of fractions	Duration of treatment
Conventional fractionation	1.8–2	Standard	Standard
Hyperfractionation	<1.8	More than one fraction per day	The same as conventional
Continuous hyperfractionated accelerated radiotherapy (CHART)	<1.8	Three fractions per day for 7 days a week	Reduced
Hypofractionation	>2	Reduced	The same or reduced

Table 5 Rationale of altered fractionation

Fractionation	Rationale	Effect on acute tissues	Effect on late tissues	Disadvantages
Conventional fractionation	To spare the normal tissue, reassortment, reoxygenation	Standard	Standard	Long treatment, chances of accelerated repopulation
Hyperfractionation	To reduce late toxicity	Standard or greater	Lower	Long treatment, chances of accelerated repopulation
CHART	To overcome accelerated repopulation	Greater	Standard	More acute toxicity, not suitable for all tumors and patients
Hypofractionation	Tumors with low α/β	Lower	Standard or higher	Propensity for higher late toxicity and need for high conformity

4 QUANTEC and Dose Constraints

Initial attempts to develop dose constraints consisted of correlating the total dose received by an organ with the percentage of risk of developing complications. Tolerance dose 5/5 represented the dose of radiation that could cause no more than 5% severe complications within 5 years of treatment. This was based on conventional fractionation. With the evolution of three-dimensional (3D) planning systems, volumetric data were available for analysis. This leads to volume-based dose constraints first developed by Emami [22]. This report consisted of minimal dose constraints for one-third, two-third, and the whole organ. There was still a need for a more robust volume-based constraint, taking into account other factors like chemotherapy. Thus, by 2010, robust data of volumetric dosimetry were accumulated, which led to qualitative analysis of normal tissue effects in the clinic (QUANTEC) [23]. The QUANTEC report consisted of constraints for 16 organs; robust follow-up data with the impact of confounding factors like chemotherapy were addressed. The concise recommendations from the QUANTEC report are presented in Tables 6 and 7.

Table 6 QUANTEC recommendations

Organ	Volume	End point	Constraint	Toxicity rate
Brain	Whole organ	Symptomatic necrosis	<60 Gy	<3%
			72 Gy	5%
			90 Gy	10%
Brain stem	Whole organ	Permanent cranial neuropathy or necrosis	<54 Gy	<5%
			<64 Gy	<5%
			D1–10 mL ≤59 Gy	<5%
Optic nerve/chiasm	Whole organ	Optic neuropathy	<55 Gy	<3%
			55–60 Gy	3–7%
			>60 Gy	>7–20%
Spinal cord	Partial organ	Myelopathy	50 Gy	0.2%
			60 Gy	6%
			69 Gy	50%
Cochlea	Whole organ	Sensory neural hearing loss	Mean dose ≤45 Gy	<30%
Parotid bilateral	Whole organ	25% Reduction in salivary function	Mean dose <25%	<20%
			Mean dose <39 Gy	<50%
Parotid unilateral	Whole organ	25% Reduction in salivary function	Mean dose <20 Gy	<20%
Pharyngeal constrictors	Whole organ	Symptomatic dysphagia and aspiration	Mean dose <50 Gy	<20%
Larynx	Whole organ	Vocal dysfunction	<66 Gy	<20%
		Aspiration	Mean dose <50 Gy	<30%
		Edema	Mean dose <44 Gy	<20%
		Edema	V50 <27%	<20%
Lungs	Whole organ	Symptomatic pneumonitis	V20 ≤30%	<20%
			Mean dose 7 Gy	5%
			Mean dose 13 Gy	10%
			Mean dose 20 Gy	20%
			Mean dose 24 Gy	30%
			Mean dose 27 Gy	40%
Esophagus	Whole organ	Grade 3 or higher esophagitis	Mean dose <34 Gy	5–20%
		Grade 2 or higher esophagitis	V35 <50%	<30%
		Grade 2 or higher esophagitis	V50 <40%	<30%
		Grade 2 or higher esophagitis	V70 <20%	<30%
Heart	Pericardium	Pericarditis	Mean dose <26 Gy	<15%
	Pericardium	Pericarditis	V30 <46 Gy	<15%
	Whole organ	Long-term cardiac mortality	V25 <10%	<1%
Liver	Whole liver—GTV	Classic Radiation Induced Liver Disease (RILD)	Mean dose <30–32 Gy	<5%
			Mean dose <42 Gy	<50%
			Mean dose <28 Gy	<5%
			Mean dose <36 Gy	<50%
Kidneys	Bilateral whole kidney	Clinically relevant renal dysfunction	Mean dose <15–18 Gy	<5%
			Mean dose <28 Gy	<50%
			V12 <55%	<5%
			V20 <32%	<5%
			V28 <20%	<5%

Table 6 (continued)

Organ	Volume	End point	Constraint	Toxicity rate
Stomach	Whole organ	Ulceration	<45 Gy	<7%
Small bowel	Individual loops	Grade 3 or higher acute toxicity	V15 <120 mL	<10%
	Entire peritoneal cavity	Grade 3 or higher acute toxicity	V45 <195 mL	<10%
Rectum	Whole organ	Grade 3 or higher late toxicity	V50 <50%	<10%
			V60 <35%	<10%
			V65 <25%	<10%
			V70 <20%	<10%
			V75 <15%	<10%
Bladder	Whole organ	Grade 3 or higher late Radiation Therapy Oncology Group (RTOG) toxicity	<65 Gy	<6%
		Grade 3 or higher late RTOG toxicity	V65 ≤50%	
			V70 ≤35%	
			V75 ≤25%	
			V80 ≤15%	
Penile bulb	Whole organ	Severe erectile dysfunction	Mean dose to 95% of the gland <50 Gy	<35%
			D90 <50 Gy	<35%
			D60–70 <70 Gy	<35%

Table 7 QUANTEC dose constraints for SBRT (single fraction)

Organ	Volume	End point	Constraint	Toxicity rate
Brain	Whole organ	Symptomatic necrosis	V12 <5–10 cc	<20%
Brain stem	Whole organ		<12.5 Gy	<5%
Optic nerve/chiasm	Whole organ		<12 Gy	<10%
Spinal cord	Partial organ	Myelopathy	13 Gy	1%
Cochlea	Whole organ	Sensory neural hearing loss	<14 Gy	<25%
Liver/hepatocellular carcinoma (HCC) (three fractions)	Whole liver—GTV	RILD	Mean <13 Gy	<5%
Liver/metastases (three fractions)	Whole liver—GTV	RILD	Mean <15 Gy	<5%
Liver (three fractions)	>700 cc	RILD	<15 Gy	<5%

5 Radiobiology of Brachytherapy

Unlike external beam radiotherapy, the dose distribution attained in brachytherapy is extremely unique. The region near the source receives an extremely high dose, whereas the region away from the source receives a much lesser dose. The dose distribution in brachytherapy is governed by the inverse square law. Thus, dose heterogeneity must be accepted with brachytherapy. This can be used as an advantage when we position the radioactive source within the tumor, thus escalating the dose to the tumor. The radiobiology of low-dose-rate brachytherapy differs considerably from that of high-dose-rate. With LDR brachytherapy, simultaneous repair occurs, which is beneficial to normal tissues, and, then, repopulation of the surviving cells occurs. Reoxygenation that occurs during prolonged LDR treatment increases the radiosensitivity of the surviving clones. Reassortment from the radioresistant phase to the radiosensitive phase also contributes to increased sensitivity. A phenomenon called the inversed dose rate effect can also occur when the cell progresses during radiation till the G2 phase where it undergoes death due to the increased radiosensitivity of the G2 phase.

6 Radiation Modifiers

The effect of radiation can be enhanced by the use of physical and chemical modifiers. Chemical modifiers include hypoxic sensitizers. Compounds with high electron affinity produce free radicals, thus sensitizing hypoxic cells to radiation. The classical example is misonidazole, which is used in many clinical trials. Perfluorocarbons are also other agents, which work on a similar mechanism. Cytotoxic agents such as actinomycin D, doxorubicin, cisplatin, etc. have shown to be efficient radiosensitizers. Radiotherapy increases the expression of epithelial growth factor receptors (EGFRs) on the cell surface; therefore, when EGFR blockers are added to radiotherapy, the effect of radiation may be potentiated. It has shown to improve locoregional control in locally advanced squamous cell carcinomas. Apart from potentiating the effect of radiation, there are some chemical compounds that act as radioprotectors, such as amifostine, which acts as a free radical scavenger. It has been used to reduce the incidence of xerostomia in patients with head and neck cancer treated with radiotherapy. Hypoxia is a known factor that has contributed to radioresistance. Thus, hyperbaric oxygen, carbogen, and nicotinamide have been used to overcome both acute and chronic hypoxia. Erythropoietin increases red blood cell production, thus increasing the oxygen-carrying capacity. Indirectly, it helps overcome hypoxia. Hyperthermia is also a useful method to mitigate radioresistance by selectively killing hypoxic, acidic, and nutritionally deprived cells.

7 The Physics of Radiotherapy

7.1 The Basic Physics of Radiotherapy

Having understood the physical and biological aspects of how radiations interact with matter, the next important aspect in physics that requires a thorough understanding is the photon beam, linear accelerator, and the basic concepts of the various processes involved in radiotherapy. Some important definitions and concepts are provided in Tables 8 and 9.

The setup of a patient for treatment is of two types, source-to-skin distance (SSD) and source-to-axis distance (SAD). In the SSD technique, the patient is set at the isocenter of the machine, 80 cm for cobalt and 100 cm for linear accelerators. Each field has to be set individually with verification of the field size on the skin. In the SAD technique, the isocenter is ideally placed at the center of the tumor and the gantry rotates around the isocenter. Thus, the patient requires to be setup for only one field. The field size seen on the skin with the SAD technique is essentially smaller than the field size at the isocenter.

Table 8 Important terms and definitions

Term	Definition
Dose	Amount of mass deposited per unit mass of material. The SI unit is Gray; 1 Gy = 1 J/kg
KERMA	Kinetic energy released in a medium expressed in Joules per kilogram
Percentage depth dose (PDD)	Ratio of the dose at a depth D_d to the maximum dose D_m along the central axis of the beam, expressed in percentage
Buildup region	Region between the incident surface and the region of maximum dose (D_{max})
D_{max}	Depth of the maximum dose also called the reference point
Field size	Distance from the field edge at the 50% isodose line with 100% normalization at the central axis of the beam
Flatness	Deviation of the dose level across the central axis of the beam
Symmetry	Deviation in the dose level of symmetric points on either side of the central axis
Penumbra	Region covered by the 80–20% isodose line
Half-value layer	Thickness of the material required to reduce the intensity of the incident beam to 50% of its original value
Isocenter	Point in space around which the axes of the gantry, collimator, and couch rotate

Table 9 Effects of various parameters on a photon beam

Parameters	Effect on a beam
Energy	Increase in PDD with increase in energy
	Surface dose reduces with increase in energy (skin sparing)
	Increase in Half Value Layer (HVL) with increase in energy
	Lesser scatter with increase in energy
Field size	PDD increases with field size
	Surface dose increases with field size
	Beam output increases with increase in field size
Penumbra	Increases as depth increases
	Increases with increase in field size
	Increases with increase in source-to-skin distance (SSD)
	Increases with the size of the source

Simulation in radiotherapy is a process by which the patient's intended treatment position is replicated with appropriate immobilization devices and an image is acquired. The acquired image can be in the form of two-dimensional (2D) X-rays, computed tomography (CT) scanning, magnetic resonance imaging (MRI), or positron emission tomography (PET) scanning. Care must be taken to simulate the treatment conditions such as identical bladder filling, rectal distention, and immobilization. When 3D images are acquired, it is advisable to take thin slices because the quality of reconstruction is better with thin slices. The acquired images are then imported into the planning and contouring station.

Treatment in radiation oncology is volume-based. Thus, a proper understanding of the concepts of volume is essential for proper planning and treatment. The International Commission on Radiation Units and Measurements (ICRU) has developed recommendations for uniform reporting of treatment parameters. The recommended volumes as per the ICRU are provided in Table 10.

As per the ICRU 83 report, it is recommended to report the $D_{near\text{-}min}$ or $D_{98\%}$ and the $D_{near\text{-}max}$ or $D_{2\%}$ for tumors, the mean dose for parallel organs at risk (OARs), and the maximum dose for serial organs. Other parameters recommended are homogeneity index (HI = (D2% − D98%)/D50%) and the conformity index (CI).

Table 10 Volumes as per ICRU

Gross tumor volume (GTV)	Volume that contains gross palpable or visible/demonstrable extent and location of malignant growth
Clinical target volume (CTV)	Region around the tumor where there is subclinical involvement by individual malignant cells, small cell clusters, or micro-extensions, which cannot be detected by staging procedures
Planning target volume (PTV)	Volume that encloses the GTV and CTV, which accounts for uncertainties in organ motion and setup uncertainties
Treated volume (TV)	Volume enclosed by an isodose surface, the value of which is the minimum target-absorbed dose
Irradiated volume (IV)	Volume that receives an absorbed dose, which is considered significant in relation to tissue tolerance (e.g., 50%) of the specified target-absorbed dose
Internal target volume (ITV)	Volume to account for variations in size, shape, and position of the CTV in relation to anatomical reference points
Organ at risk (OAR)	Normal tissue at risk of radiation-induced morbidity
Planning organ at risk volume (PRV)	Volume to account for variations in OAR motion and setup uncertainty

8 External Beam Radiography

External beam radiotherapy is delivered with the help of telecobalt or linear accelerators. The construction of a telecobalt unit consists of a radioactive telecobalt source housed in a shielded gantry. The cobalt source is a cylindrical double-walled sealed source of 3-cm diameter and 5-cm height. The half-life of Co-60 is 5.2 years. The source is kept in a shielded gantry, and, on initiation, it is moved to the gantry head with the help of a pneumatic system. The gantry contains collimators, which help in determining the field size. The maximum field size is 35 × 35 cm^2 at 80-cm SSD. An emergency T-bar is provided, which can be used to push the source in case of mechanical failure. The unit is isocentrically mounted and can rotate 360° along the isocenter. In contrast, a linear accelerator consists of a target with a high atomic number, such as tungsten, which produces X-rays by bremsstrahlung interactions. The electrons are produced by thermoluminescence from an electron gun. They are accelerated with the help of microwaves produced by a magnetron (<10 MV) or a klystron. These microwaves accelerate the electrons in the wave guide. Based on the energy of the photons, there may be bending magnets before the electrons strike the target. The target is of transmission type, which is placed on a carrousel with a scattering foil when electrons are required for treatment. A flattening filter is placed below the target to harden the beam and to produce a uniform intensity across the beam profile. Newer accelerators have the provision for flattening the filter-free option, which leads to increased output and an inhomogeneous beam profile. Monitor chambers are placed below the flattening filter to monitor the amount of radiation exiting the machine and also to check for symmetry. Collimators are present below along with Multileaf Collimator (MLC) for shaping of the treatment field. A modification of the modern linear accelerator is TomoTherapy. It comprises a circular ring CT gantry mounted on an isocenter. It is a single-energy (6-MV) accelerator, which produces a fan-shaped beam. Thus, the volume of interest is treated slice by slice with continuous movement of the couch. The MLC in TomoTherapy is binary and consists of only an on or off position. Verification of the target position can be done before treatment with the help of 2D orthogonal X-rays [electronic portal imaging devices (EPIDs)], a cone or a mega-voltage (MV) fan beam, and a CT scanner. The process of verification of the target before treatment and then appropriately matching the treatment volume with the help of onboard imaging is called IGRT.

The treatment fields in radiotherapy have evolved from conventional open fields to highly conformal intensity-modulated fields. Conventional radiotherapy fields consist of open fields with minimal sparing of the normal tissue. Custom-made blocks had to be developed to shape the fields appropriately to spare the normal tissue. With the advent of MLCs, the shaping of multiple fields has become easy, thus leading to the development of 3D conformal radiotherapy. However, optimal sparing of OARs was still not achievable. There was still a high-dose region at the field junctions and dose inhomogeneity over irregular surfaces. Intensity-modulated radiotherapy consists of dividing the entire field into multiple beamlets and modulation of the photon intensity across each beamlet with the help of MLC motion. Thus, an inhomogeneous field can be developed, which can be adapted to clinical requirements (Fig. 1). IMRT initially started with a static field step and shoot IMRT, but, with further advancements, the MLC motion could be synchronized with the motion of the gantry, thus leading to the development of volumetric modulated arc therapy (VMAT). This led to shorter treatment times and highly conformal treatment plans.

For stereotactic radiotherapy (SRT), more sophisticated linear accelerators and cobalt units have been developed, namely, the LINAC radiosurgery unit and the gamma stereo-

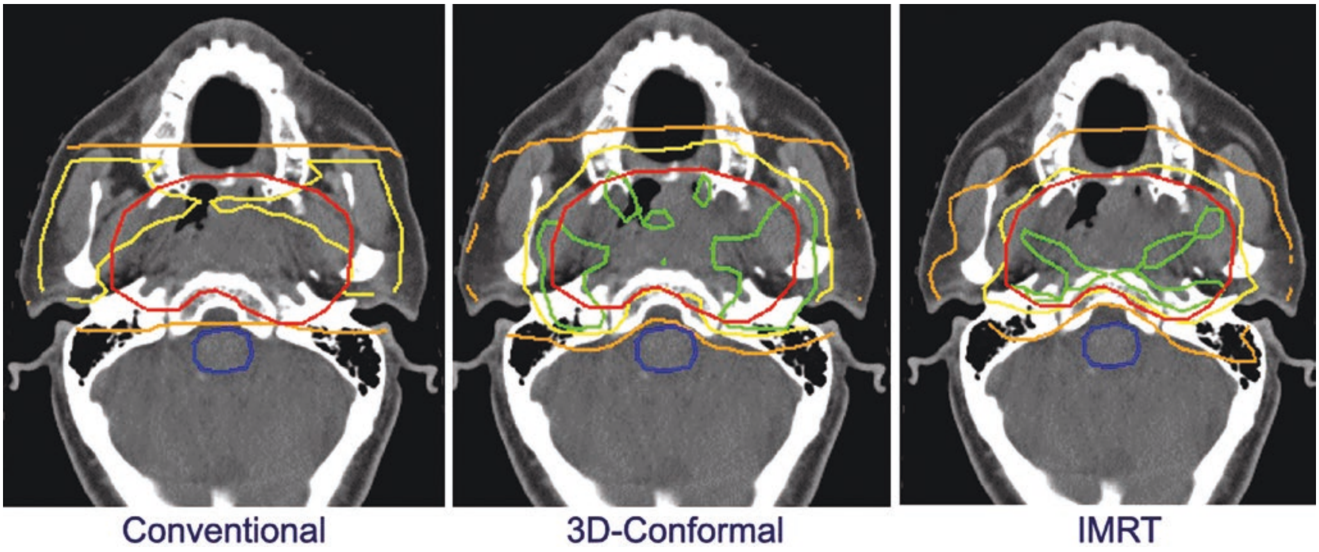

Fig. 1 Dose distribution comparing conventional 3D-conformal technique and intensity-modulated radiotherapy plans

tactic radiosurgery (SRS) unit. The gamma radiosurgery unit consists of 30–200 Co-60 sources arranged in a hemispherical pattern focusing on an isocenter. The source-to-focus distance is 40 cm. The LINAC radiosurgery unit consists of a linear accelerator mounted on a mobile gantry. There is a circular tertiary collimator that opens to form circular fields at 77 cm from the target.

Recently, there has been growing interest in the use of charged particles for delivering external beam radiation therapy. The greatest physical advantage of particle therapy (e.g., protons) over conventional X-ray therapy is the sharp fall-off of the radiation dose beyond the target tissue with particles compared to X-rays, thus allowing better sparing of the normal tissues. Heavy particles like carbon ions have an added biological advantage over X-rays. Heavy ions have a greater efficiency in cell kill (RBE) compared to X-rays, and they remain efficacious even in the absence of oxygen (OER).

9 Brachytherapy

The term "brachytherapy" originates from "brachy," meaning short, hence implying short-distance therapy. In brachytherapy, the radioactive source is kept within or in the vicinity of the tumor. The advantages of brachytherapy over external beam radiotherapy are that the dose fall-off with increasing distance is extremely steep. Photons produced by brachytherapy sources have extremely low energies and are attenuated extremely easily. The inhomogeneous dose profile produced by brachytherapy can be used to escalate the dose to the tumor while sparing the OARs. Historically, radium sources were used for brachytherapy, which involved inadvertent exposure of the oncologist and also required extensive shielding. With the development of artificial radioactive sources like cesium and iridium, the use of radium has declined. Development of remote after-loading techniques has reduced the radiation exposure of physicians considerably. Unlike external beam radiotherapy, the dose prescribed for brachytherapy has been developed from the amount of the radioactive source and the duration of the treatment. This was relevant in the radium era, but, with the development of artificial isotopes with varying dose rates, the calculations based on radium are not reliable. Hence, a new term, "Total Reference Air Kerma (TRAK)," was developed. It is the integral of the reference air kinetic energy released in a medium (KERMA) over the treatment duration for all source positions. The absorbed dose at any point is directly proportional to TRAK. Conversion of radium equivalent hours (mgHr) to TRAK uses a constant of 7.227 mGy. Systems in brachytherapy are a set of rules for implanting and prescribing radiation. There are two main methods of brachytherapy, i.e., interstitial and intracavitary brachytherapy. The commonly followed system for interstitial brachytherapy is the Paris system. It describes the ideal geometry of an implant such as in squares or triangles to obtain an ideal dose distribution. A concept introduced is the basal dose rate, which is the dose rate at the center of the treated volume at the central plane. The reference dose rate is 85% of the basal dose rate for which the implant is prescribed. Treatment volume is the volume enclosed by the 85% isodose line. The hyperdose sleeve is the region covered by the 170% isodose line. Interstitial brachytherapy is widely used for many cancers like head and neck, soft tissue sarcoma, and breast.

Intracavitary brachytherapy for carcinoma of the cervix is one of the most commonly used indications of brachytherapy. It has transitioned from X-ray-based 2D planning and point-based prescription to 3D volumetric image-

Table 11 Dose points used in carcinoma of the cervix

Points	Description
POINT A (Original Manchester 1938)	It is 2 cm lateral to the central canal of the uterus and 2 cm up from the mucous membrane of the lateral fornix in the axis of the uterus
Revised Manchester point A (1953)	It is 2 cm superior from the lower end of the ventral radium tube and 2 cm lateral from the uterine canal
ABS point A	Draw a line connecting the middle of the vaginal source on the anterior–posterior (AP) radiograph and move 2 cm plus the radius of the ovoid superiorly along the tandem from the intersection of this line with the intrauterine source line and then 2 cm lateral on either side of the tandem
Point B	At the same level of point A but 5 cm from the midline
Point P	The same plane as point A but 6 cm lateral to the midline

Table 12 ICRU 89 volumes

GTVinitial	Gross macroscopic disease at presentation
GTVres	Macroscopic residual disease after 45–50 Gy of External Beam Radiation Therapy (EBRT)
High-risk CTV	Whole cervix, residual GTV, residual pathological tissue
Intermediate-risk CTV	GTVint, HR CTV + margins to account for the microscopic residual disease in the region outside the HR CTV
Low-risk CTV	Entire cervix, body of uterus, parametrium, and upper one-third of the vagina

guided brachytherapy prescription. The classical point A described in the Manchester system has evolved over time. Table 11 provides the various dose points used in brachytherapy of carcinoma of the cervix. The current Group European de Curitherapie-European Society for Radiotherapy & Oncology (GEC-ESTRO) and ICRU 89 reports recommend volumetric reporting of brachytherapy dose prescription. Table 12 highlights the various volumes for reporting according to ICRU 89.

10 Special Techniques and Technologies in Radiation Oncology

10.1 Total Skin Electron Therapy (TSET)

This technique of external beam radiation therapy is used for treatment of the entire skin surface or a part of it. The most common indication is for treatment of mycosis fungoides. The six-field, modified Stanford technique is used most frequently. This technique uses 4–6-MeV electrons with the patient standing in predefined positions at an extended SSD of 300–400 cm. Two different beam angles are used to adequately encompass the entire body surface. A beam spoiler is placed in the beam path close to the body surface in order to increase the skin dose. Areas that are underdosed (the scalp, sole, perineum, etc.) may require an additional boost dose to prevent underdosing. A detailed technical description is available in the American Association of Physicists in Medicine (AAPM) Report No. 23.

10.2 Stereotactic Radiosurgery (SRS)/Stereotactic Radiotherapy (SRT)

These are techniques to administer precise, high-dose radiation that tightly conforms to the target. This technique is based on the fact that radiation tolerance is volume-dependent. The term “radiosurgery” is used when the treatment involves a single fraction regimen, whereas the term “radiotherapy” is used when multiple fractions are delivered. The first stereotactic radiosurgery equipment was designed by Leksell in 1967 where multiple cobalt sources were placed in a hemispherical array. A LINAC-based radiosurgery model was designed in 1980; it consisted of a linear accelerator mounted on a robotic arm that could move in six axes. The image-processing system had two orthogonal X-rays to track the target. Clinically, these techniques are used in the management of benign conditions like trigeminal neuralgia, Arterio Venous Malformation (AVM), schwannoma and also for malignant lesions like metastasis.

10.3 Stereotactic Body Radiotherapy (SBRT)

It is the use of image-guided high-dose radiotherapy with tumor-ablative intent and the maximum number of fractions not exceeding five. This is used in tumors that have an extremely low α/β such as prostate. It is also currently employed in treating extremely early tumors that have small treatment volume and also in oligometastatic disease. There are specific American College of Radiology/Americal Society for Therapeutic Radiology & Oncology (ACR/ASTRO) guidelines for those who wish to practice SBRT routinely. High precision is required in the SBRT; hence, adequate immobilization and target motion management with appropriate gating methods, as in the lung or deep inspiratory breath hold as in the pancreas, are necessary. Currently, SBRT is making inroads into sites like the liver, lungs, pancreas, and oligometastatic sites.

10.4 Total Body Irradiation (TBI)

This is a highly novel technique of irradiating the entire body to a homogeneous dose. The most important indication currently is a conditioning method before stem cell transplantation. Based on the total dose of radiation used, TBI can be classified as either myeloablative (e.g., 12 Gy) or non-myeloablative (e.g., 2 Gy). TBI has a dual effect in the form of cytotoxicity and immune modulation and remains effective against malignant cells located both at sanctuary and non-sanctuary sites. The most fatal and dose-limiting toxicity of TBI is pulmonary toxicity. There are higher rates of pulmonary toxicity, with those having underlying pulmonary dysfunction, busulfan, and cyclophosphamide-based conditioning regimen. Lowering the dose rate to <0.025 Gy/min has been shown to reduce pulmonary toxicity along with reduction in the total dose. A detailed description of the physical aspect of TBI is provided in AAPM TG 17.

Systemic Treatment of Cancer

Shona Nag and Sudeep Gupta

Abbreviations

ADC	Antibody drug conjugate
ADCC	Antigen-dependent cellular cytotoxicity
AML	Acute myeloid leukemia
B-ALL	B-cell acute lymphocytic leukemia
B-CLL	B-cell chronic lymphocytic leukemia
CAR-T	Chimeric antigen receptor T cell
CDCC	Complement-dependent cytotoxicity
CML	Chronic myelogenous leukemia
DHT	Dihydrotestosterone
ER	Estrogen receptor
FSH	Follicle-stimulating hormone
LH	Luteinizing hormone
LHRH	Luteinizing hormone-releasing hormone
NHL	Non-Hodgkin's lymphoma
PR	Progesterone receptor

1 Introduction

Cancer is a systemic disease. This implies that although the manifestation of a tumor may be local, i.e., a breast lump or a rectal mass, if treated only with local therapy such as surgical removal, then there is a reasonable chance of metastasis developing in the future. The likely explanation for the development of metastasis is the presence of residual microscopic disease, which grows over time to present as widespread metastatic disease. The treatment that addresses this microscopic disease and delays or prevents a relapse is referred to as "systemic treatment" for cancer. It is often referred to as adjuvant cancer treatment, as it follows the initial treatment of a tumor, which could be in the form of a surgery or local radiation therapy. The goal of this treatment is cure. Systemic treatment can also be administered to cancers that are already advanced or metastatic. In this setting, it is called palliative therapy, and the major goals are symptom control and prolongation of life.

2 The History of Systemic Treatment

There are three observations that have contributed to modern cancer systemic therapy as we know it today. The first was made by Paul Ehrlich in the nineteenth century who coined the term "chemotherapy" for compounds or magic bullets that demonstrated activity against parasites, causing the maximum toxicity to the pathogen and least to the host [1, 2]. He is considered the father of chemotherapy.

The second observation was made in 1896 by an English surgeon, George Beatson, who performed an oophorectomy in a 33-year-old woman with advanced breast cancer who went on to live for 4 years after the operation [3]. He performed other similar surgeries and concluded that women with breast cancer benefitted from this approach, providing that they were carefully selected [4]. This observation formed the foundation of hormonal therapy for breast cancer as it is practiced today.

The third observation took place during World War I, when the toxic effects of mustard gas used for combat resulted in hypoplasia of the bone marrow and lymph nodes. This agent was then used to treat a patient with non-Hodgkin's lymphoma (NHL) in 1942 and, subsequently, showed dramatic regressions in lymphomas, thus generating considerable enthusiasm in the pharmacology of cancer.

3 Types of Cancer Systemic Therapies

Systemic cancer treatment can be categorized into four different types

1. Conventional cancer chemotherapy—targets the DNA structure of the cancer cell
2. Hormonal therapy—attacks the biochemical pathways underlying the estrogen and androgen functions
3. Targeted therapy (also known as biological therapy)—a key pathway or process driving the growth of a particular tumor is interrupted
4. Immunotherapy—harnesses the body's own immune system to fight the cancer cells

Table 1 shows the categories of systemic therapies available and in clinical use at present.

Table 1 Systemic therapies in current clinical use

Systemic therapy	Class	Examples
A. Cytotoxic chemotherapy	Antifolates	Methotrexate
	5-Fluoropyrimidines	5-Fluorouracil
	Cytidine analogues	Cytosine arabinoside
	Purine antimetabolites	6-Mercaptopurine
	Hydroxyurea	
	Antimitotic drugs	Vincristine, paclitaxel
	Alkylating agents	Cyclophosphamide
	Platinum analogues	Cisplatin, carboplatin
	Antitumor antibiotics	Bleomycin
	Topoisomerase 1 inhibitors	Topotecan
	Topoisomerase 2 inhibitors	
	Anthracyclines	Doxorubicin
	Epipodophyllotoxins	Etoposide
	Asparaginase	L-Asparaginase
B. Hormonal therapy	Selective estrogen receptor modulators	Tamoxifen
	Antiestrogens	Fulvestrant
	Aromatase inhibitors	Letrozole
	LHRH agonists	Goserelin
	Antiandrogens	Bicalutamide
	Steroidogenesis inhibitors	Abiraterone acetate
C. Molecular targeted therapies	Proteosome inhibitors	Bortezomib
	Histone deacetylase inhibitors	Vorinostat
	Differentiating agents	ATRA
	Arsenic trioxide	
	Monoclonal antibodies	Rituximab
	Angiogenesis inhibitors	Bevacizumab
	EGFR (epidermal growth factor receptor) inhibitors	Gefitinib
	Her2 inhibitors	Trastuzumab
	Molecular targeted drugs	Imatinib
D. Immunotherapy	Cytokine therapy	Interferons
	Cancer vaccines	HSP/peptide vaccine
	Adoptive cellular therapies	CAR-T cell therapy
	Checkpoint inhibitors	Pembrolizumab

4 Settings for Cancer Systemic Treatment

Primary or Induction Therapy: This is the first treatment for patients who present with advanced cancers, for which there is no other alternative therapy, e.g., chemotherapy for acute leukemias and chemotherapy for germ cell tumors.

Neoadjuvant Therapy: This is the use of systemic treatment, usually chemotherapy, administered before a definitive local treatment such as a surgery or radiotherapy in order to shrink the tumor, thus allowing for higher rates of surgical resection and eradication of micrometastasis, e.g., chemotherapy for osteogenic sarcoma and for breast cancer.

Adjuvant Therapy: This is the use of systemic therapy after definitive local treatment to eradicate micrometastasis in order to improve cure rates, e.g., hormonal therapy for breast cancer and colon cancers and targeted therapy for ovarian cancer.

Palliative Therapy: This is the use of systemic therapy for advanced tumors in order to mitigate symptoms and prolong survival, e.g., targeted therapies and immunotherapy for non-small cell lung cancer and renal cell carcinoma.

Concurrent Therapy: This is administered along with radiation to improve response rates and survival, e.g., concurrent chemotherapy administered during radiation for cervical cancer.

Table 2 shows the tumors and the main clinical settings where chemotherapy has had the largest impact.

This chapter will describe the principles underlying each type of treatment and highlight the key concepts supporting their use.

Table 2 Clinical settings in which systemic therapy has the largest impact

A. In the adjuvant setting after surgery
Breast cancer
Colorectal cancer
Gastric cancer
Ovarian cancer
Pancreatic cancer
Testicular cancer
B. In the neoadjuvant setting for locally advanced disease
Osteogenic sarcoma
Breast cancer
Bladder cancer
Head and neck cancer
Gastroesophageal cancer
Rectal cancer
C. In the advanced or metastatic setting
Non-small cell lung cancer
Breast cancer
Pancreatic cancer
Colorectal cancer
Nasopharyngeal cancer
Prostate cancer
D. As the primary treatment modality
Acute leukemia
Non-Hodgkin's lymphoma
Small cell lung cancer
Myeloma
Embryonal rhabdomyosarcoma
Germ cell cancer

5 The Principles of Chemotherapy

5.1 Cancer Cellular Kinetics

It is important to understand the distinct growth patterns of normal and tumor cells. Both share the property of having two types of cells: those that actively divide and progress through the cell cycle, resulting in growth, and those in the resting or dormant phase. Some of these resting cancer cells are the cancer stem cells responsible for relapses and are difficult to eliminate as they are highly resistant to conventional systemic therapies.

Various model systems have been developed to describe the growth pattern of cancer cells. Skipper et al. [5] used murine leukemia L1210 cells as their first experimental model system in order to describe cancer cell kinetics. Based on their findings with this model, the cytotoxicity of cancer chemotherapy followed a logarithmic or exponential cell kill or first-order kinetics. What this means is that a given dose of a chemotherapeutic drug kills a constant proportion or a fraction of a cancer cell population and not a constant number. Therefore, every time a drug is administered, it destroys a fixed percentage of cells rather than a fixed number. This phenomenon is also referred to as log kill. For example, if a particular cancer drug has a 3-log kill, then it will reduce the cancer cell population from 10^{12} to 10^9 cells. Similarly, a tumor burden of 10^5 cells would come down to 10^2 cells with the same treatment. This model also established an important caveat for chemotherapy—cure with chemotherapy was inversely proportional to the cell number or tumor burden. This model also assumes that growth fraction, i.e., the proportion of cells in a tumor, which are dividing, remains constant.

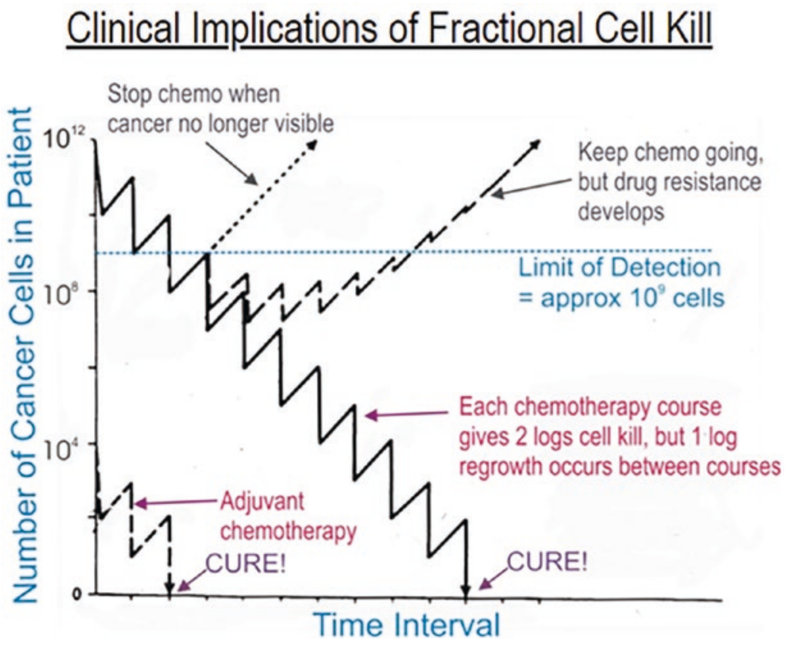
The fractional kill hypothesis has important clinical implications (Fig. 1). It appears that the chances of cure are the highest when tumor burden is low, e.g., after surgery. For the tumor to be clinically detectable, it has to grow to a size of 10^9 cells. In this case, each session of chemotherapy provides a cell kill of 2 logs, but the problem is that the time interval between the administration of two chemotherapies allows tumor regrowth of 1 log. Often, resistance develops with continuation of chemotherapeutic treatment.

However, human solid tumors do not follow first-order kinetics. The data for solid tumors support the Gompertzian model of growth. The main difference between the exponential and the Gompertzian model is that the growth fraction in the Gompertzian model is not constant but decreases with time. In this model, it is stipulated that the growth fraction of the tumor is the highest when the tumor reaches 37% of its maximum size. Thereafter, the growth fraction slows down and plateaus before decreasing. The possible explanation for this is the lack of oxygen, blood supply, and nutrients to which the tumor has access as its size grows. The clinical implication is that the response of a solid tumor to chemotherapy depends on which part of the growth phase it has been diagnosed at—making smaller tumors more chemosensitive as they have a larger growth fraction. However, regrowth would also be faster between chemotherapy cycles for smaller tumors, thus underscoring the fact that size alone is not the only determinant to administering adjuvant chemotherapy (Fig. 2).

5.2 Rationale for Chemotherapeutic Combinations

It is well-established that single chemotherapeutic drugs are unable to cure cancer. The early combination therapies were not very effective due to a paucity of available active agents. Later, this problem was overcome and a number of rational chemotherapeutic combination regimens were developed for several tumor types. The advantages of using chemotherapeutic combinations are manifold:

1. Each chemotherapeutic agent can be used in full doses within the toxicity range, leading to the maximum cell kill of the tumor.



Clinical Implications of Fractional Cell Kill
Number of Cancer Cells in Patient
10^{12}
10^{8}
10^{4}
0
Stop chemo when cancer no longer visible
Keep chemo going, but drug resistance develops
Limit of Detection = approx 10^{9} cells
Each chemotherapy course gives 2 logs cell kill, but 1 log regrowth occurs between courses
Adjuvant chemotherapy

Fig. 2 The Gompertzian model for solid tumors

2. As thetumor is genetically heterogeneous, the use of combination chemotherapy allows drug and tumor cell interaction at several levels.
3. Combination chemotherapy has the potential to delay or prevent the development of resistance.

The selection of different chemotherapeutic drugs to be used in combination also follows certain principles. First, only drugs that have been proven to be effective in treating that particular tumor type are to be included in combination with each other. Drugs that are likely to produce complete responses in at least a fraction of the patients are preferable to those that produce partial responses. Lastly, drugs with nonoverlapping toxicities are selected for combination therapies.

Other important aspects while choosing chemotherapeutic drug combinations are as follows

1. A good understanding of the biochemistry and pharmacokinetics and interactions between the drugs in the combination chosen.
2. Arbitrary reduction of doses of a drug in a combination may dramatically compromise the efficacy of the combination.
3. The interval between two doses of chemotherapy is simply to allow the bone marrow of the host to recover for the next dose to be administered and is usually 3 weeks. This interval can be shortened by the use of growth factors.
4. The duration of chemotherapy administration depends on the clinical situation. It can vary between 4 and 6 months in the adjuvant setting. For metastatic disease, chemotherapy is usually continued until disease progression or unacceptable toxicity.
5. It is vital to determine the therapeutic index of the drug. This is defined as the comparison between the amount of drug required for the therapeutic effect and the amount required to cause toxicity. Really useful drugs have a large therapeutic index. Unfortunately, most chemotherapeutic drugs have a narrow therapeutic window and toxicities have to be kept in mind while combining them.

5.3 The Concept of Dose Intensity

Effective dosing of chemotherapy is critical to achieve cure. The dose–response curve in most biological systems is sigmoidal, as shown in Fig. 3, with the maximum effect occurring during the linear phase. Therefore, any dose reduction during this period may eventually lead to a relapse. In fact, it has been shown in experimental systems that a dose reduction of 20% can result in a 50% reduction in cure rate even though the response rates may be maintained. The steeper the curve, the more likely it is that a dose reduction of the drug is going to impact its therapeutic efficacy. Therefore, empiric modifications of doses during anticancer treatment can substantially compromise outcomes.

The concept of dose intensity was introduced by Hryniuk and Goodyear [6, 7]. They defined the dose intensity of chemotherapy as the amount of drug delivered per unit of time expressed as milligram per square meter per week, irrespective of the schedule or route of administration. The dose intensity of each drug in the combination can thus be calculated. However, more important than the intended dose intensity, it is the received dose intensity that matters. There is a nice correlation between the received dose intensity in the clinical setting and the response rates of many tumors. The received dose intensity also reflects dose delays and dose reductions in the clinic and the feasibility of using the regimen in daily practice.

Summation dose intensity [8] refers to the sum of the dose intensities of the individual drugs in the chemotherapeutic combination and is useful in the design and interpretation of clinical trials.

There are three approaches to delivering chemotherapy in a dose-intensive manner

1. Dose escal3ation: The doses of the anticancer drug are increased keeping the interval between the doses the same.
2. Dose dense [9]: The interval between the doses is shortened, but the dose of the drugs is kept the same. The advantage of this approach is to prevent the regrowth of the tumor that occurs in between two doses, hence possibly avoiding the development of resistant clones emerging.
3. Sequential scheduling: Single agents are given in sequence and not in combination—therefore, the full dose intensity of each drug is maintained.

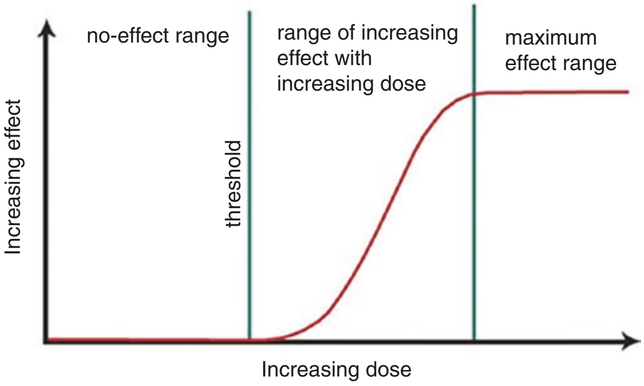

Fig. 3 The dose–response curve of a biological system

5.4 Cell Cycle and Chemotherapeutic Agents

Although the details of cell cycles are discussed elsewhere, it is worthwhile remembering a few salient aspects of their relationship with chemotherapeutic drugs. Most chemotherapeutic drugs act on tumor cells, which actively divide or undergo cell cycling. Drugs that act on specific phases of a cell cycle are called cell cycle phase-specific drugs. These act on tumors with a high growth fraction. Some drugs are however non-cell cycle-specific and these act on cells in both the resting (G0) and proliferating phases and are useful in treating tumors with a low growth fraction.

When the majority of cells in a tumor are in the G0 or resting phase, they are able to survive the toxic killing effects of chemotherapy and later regrow and produce tumor resistance.

6 The Principles of Hormonal Therapy for Cancer

Hormonal therapies that act through effects on steroid pathways and cancers that respond to this form of treatment are those arising in the organs that are heavily influenced by hormones, namely, breast cancer, prostate cancer, and endometrial cancer. Tumors arising from hormone tissues account for almost 35–40% [10] of all cancers, and these include breast and prostate cancers, which are the two most common cancers in women and men, respectively (Fig. 4).

Following Beatson's case reports on oophorectomy for breast cancer, there were several other case series and nonrandomized studies that took place in the adjuvant setting as well. In 1948, Paterson reported the first randomized trial of ovarian ablation in breast cancer at Christie Hospital, Manchester [11]. However, it was not until the early 1980s that the Oxford collaborative group was established, which brought together all the trials of chemotherapy and hormonal therapy for operable breast cancer [12].

In 1941, C. Huggins published pioneering work on the effect of castration, estrogen, and androgen injections on prostate cancer [13]. He won a Nobel Prize for his work in 1966.

Fig. 4 The pathological basis for hormone-induced cancers

6.1 The Concept of Hormone Dependence

The carcinogenic effect of hormones has been demonstrated in both animals and humans. Hormones play a role in the origin and growth of tumors and cancers of the breast, uterus, prostate, anterior pituitary, adrenal cortex, ovary, and testis and can be induced by altering the endocrine milieu of the organ. In 1959, Furth et al. described the effect of hormones on various stages of development from normal cells to hyperplasia to a hormone-dependent tumor to an autonomous tumor still dependent on hormones and finally to a fully autonomous hormone-independent tumor [14]. This concept of hormone dependency is peculiar to certain cancers, and systemic hormonal therapies have been developed by taking advantage of this property.

There are two methods of destroying tumors by endocrine manipulation

1. Hormone deprivation
2. Hormone interference

It is important to understand the fundamental difference between a normal hormone-responsive target cell and its malignant hormone-dependent counterpart. For normal cells, hormones act as catalysts that help in growth and metabolism, but, when absent, the cell still survives. In contrast, malignant hormone-dependent cells are dependent for their survival on these hormones and often die when the source of hormones is removed. Hormone deprivation in breast or prostate cancers relies on this property to effectively kill these cancer cells.

Interestingly, supplying an excessive amount of hormones to the cancer cell can also kill it. This is known as hormone interference and is toxic to cancer cells leaving normal cells relatively unaffected. An example is breast cancer where the administration of excess estrogen can actually cause regression of the tumor. Not all hormone-dependent tumors respond to hormone interference, however.

Endocrine therapies are based on two principles

1. Ligand depletion—This can be achieved in three ways. By surgically removing the source of hormones, i.e., oophorectomy or orchiectomy, by blocking the trophic hormones in the pituitary gland using luteinizing hormone-releasing hormone (LHRH) analogues, or by inhibiting enzymes involved in steroid hormone synthesis.
2. Receptor blockade—This can be achieved using sex hormone receptor blockade like antihormonal agents.

6.2 The Effects of Hormonal Therapies on the Cell Cycle

As alluded to earlier, chemotherapeutic drugs have been described as either cell cycle phase-specific or cell cycle phase-nonspecific. Antiestrogens arrest the cell cycle in the G0/G1 phase, leading to growth inhibition of the tumor cell by decreased Rb phosphorylation [15]. This, in turn, results in fewer cells entering the S phase of the cell cycle. Further credence is given to this mechanism as the effect of antiestrogens can be reversed by the addition of estradiol, which rescues the tumor cell and allows it to enter the S phase within a few hours of its exposure. Antiestrogens inhibit the incorporation of thymidine into the DNA of estrogen receptor (ER)-positive breast cancer cells, thereby halting their growth and proliferation. Therefore, they are cytostatic rather than cytotoxic, causing tumor cell arrest in the early G1 phase and thereby decreasing the amount of cells synthesizing DNA in the S phase of the cell cycle [16].

Tumor cells that are in the actively dividing phase are thus sensitive to antiestrogens, but those that are in the plateau phase of the growth curve remain relatively resistant to these agents.

6.3 Breast Cancer and the Estrogen Receptor

When a breast cell undergoes a malignant transformation, it can retain all or some of its estrogen receptors or none at all. If the malignant cell expresses any amount of the target receptor, then its growth is still dependent on estrogen and these tumors respond to endocrine therapy. In case the receptors are lost during malignant transformation, the cell is independent of estrogen and these tumors fail to respond to endocrine treatment. Therefore, receptor assays must be part of the evaluation in all breast cancers. The development of antiestrogens was an important landmark in the therapy of breast cancer.

The principles underlying hormonal therapy of breast cancer include the following

- The tumor tissue must express hormone receptors for these drugs to be useful in breast cancer. No benefit is seen in tumors that do not express hormone receptors.
- Tumors that respond to previous hormonal therapy are likely to show responses to subsequent hormone treatments on progression.
- Fast-growing tumors with large-volume visceral involvement are less likely to respond to endocrine therapy.
- It is possible to get a “flare” reaction in the first few weeks of hormonal therapy with worsening of the symptoms such as bone pain. This is not an indication to discontinue treatment.
- Withdrawal responses may be observed in hormone-responsive tumors.
- It is possible to reverse endocrine resistance in the clinic by combining hormonal agents with targeted drugs.
- The combination of two hormonal agents has not been shown to be superior to using a single drug, except in the case of combining LHRH analogues with antiestrogens in premenopausal women.
- As long as the target receptor is expressed, endocrine therapy is useful in all clinical settings of breast cancer—neoadjuvant, adjuvant, and metastatic.
- Hormonal agents are not generally combined with chemotherapeutic agents as this combination may be detrimental.

6.4 Prostate Cancer and the Androgen Receptor

The androgen receptor is the target receptor for advanced prostate cancer, and both testosterone and dihydrotestosterone (DHT) bind to the receptor, leading to tumor growth. However, most antiandrogens are incomplete or partial androgen antagonists. Moreover, suppressing the testicular source of androgen does not work for long as androgens are also secreted by the adrenal glands, and, therefore, both these sources need to be blocked in order to inhibit tumor growth.

A major breakthrough in endocrine therapy was that LHRH released in a pulsatile manner controls the secretion of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) by the pituitary gland. If, on the other hand, LHRH is released in a continuous manner, then the pituitary gets desensitized and the secretion of LH and FSH decreases rapidly. The advent of LHRH agonist analogues has helped in achieving medical castration in men and oophorectomy in women.

It was also observed that patients with prostate cancer, who initially responded to antiandrogen treatment and subsequently progressed, then responded to the withdrawal of the antiandrogen. This is known as the antiandrogen withdrawal syndrome, which suggests that even after the antiandrogen therapies stop working the androgen receptor still plays a major role in the progression of tumor cells.

Most patients will progress within 18 months of antiandrogen therapy. These tumors still retain the androgen receptor, and, in some cases, it even tends to be overexpressed. Progression of the tumor despite antiandrogen therapy can be due to androgen receptor (AR) activation by other ligands, acquired hypersensitivity to androgen, or an activation of other autocrine pathways, such as fibroblast growth factor receptor (FGFR) or epidermal growth factor receptor (EGFR), etc.

The principles underlying hormonal therapy for prostate cancer include the following

- Unlike breast cancer, checking for the presence of the androgen receptor has no benefit in the use of hormonal therapy for prostate cancer as this receptor is expressed in the cytoplasm of prostate cancer cells.
- Blockage of testosterone is the basis of all treatments in advanced prostate cancer. Even if the tumor becomes hormone- and or castrate-resistant, androgen blockade has to be continued.
- In contrast to breast cancer, sequential responses to different hormonal therapies for prostate cancer are less common.
- Androgen blockade is useful in all clinical settings for prostate cancer—neoadjuvant, adjuvant, and metastatic.
- Responses to hormonal therapy are slow, generally taking 6–8 weeks.
- A flare reaction is commonly seen on initiation of antiandrogen therapy in the first few weeks of treatment. Special care should be taken in certain clinical situations like urinary obstruction or impending cord compression.
- Withdrawal responses are commonly seen but are rarely sustained.
- Despite the use of chemotherapy, androgen blockade cannot be discontinued.

6.5 Hormones and Other Tumors

Estrogen receptor (ER) and progesterone receptor (PR) expression is seen in a wide variety of solid tumors, including gynecological tumors. Progesterone agents have been useful in stabilizing disease in metastatic endometrial cancer, and patients with low-grade indolent disease are more likely to respond. A recent meta-analysis of 39 studies has shown a duration of response of about 3 months with a median survival of about 10.8 months. Response rates ranged from 26% in ER-positive patients and 35% in patients expressing PR [17]. Tamoxifen, however, has not proven useful. The use of hormonal agents in ovarian cancers has been disappointing.

Although ERs have also been detected in hepatocellular carcinoma, lung cancer, meningiomas, renal cell carcinomas, and sarcomas, there is little evidence for endocrine therapy use in these indications.

7 The Principles of Targeted Therapy for Cancer

This section deals with targeted therapy for cancer, which has gained momentum in the last 15 years. Chemotherapy for cancer depends on drugs that lack selectivity for tumor cells and primarily consists of cytotoxic agents that have a narrow therapeutic index as described earlier. Recent efforts have focused on exploiting biological processes or targets specific for tumor cell growth. Although these drugs have proven useful for both hematological [chronic myelogenous leukemia (CML)] malignancies and solid tumors, they are not without toxicity to normal tissues, albeit different to those caused by chemotherapy.

Targeted therapies have demonstrated their usefulness in both adjuvant and metastatic settings. An increased knowledge of cancer biology has led to identifying various proteins and pathways essential to the survival of cancer cells. Targeting these proteins and pathways is the mainstay of targeted molecular therapy [18–20]. Table 3 shows the types of molecular targeted agents that have been developed.

7.1 Druggability of Molecular Targets

The most important step in developing a successful targeted treatment is validation of the target in experimental systems. Thereafter, the "druggability" of the target needs to be determined. Targeting a single protein may be limiting in its efficacy unless there is "oncogene addiction" [21]. This refers to the complete dependence of the tumor cell on a particular protein for its survival and proliferation. The inhibition of the BCR-ABL protein by imatinib in chronic myeloid leukemia is an exemplary example of oncogene addiction, and, since its development, there have been few similarly effective drugs for other indications. Oncogene addiction also explains why the tumor continues to benefit from sustained inhibition of the pathway that it is dependent on, despite clinical progression (e.g., trastuzumab can be used beyond progression in human epidermal growth factor receptor 2 (Her2)-positive metastatic disease).

Table 3 Types of molecularly targeted compounds that have been developed

Agent	Potential target(s)	Comments
Antisense oligonucleotides	RNA, DNA and proteins	Not fulfilled their promise as therapeutic agents
SiRNA	RNA	In early clinical trials
Gene therapy	Neoplastic cells, immune mediator cells	Oncolytic viruses have been used in the treatment of malignant gliomas
Ribozymes and DNAzymes	RNA and DNA in tumour cells	Angiozyme most widely studied. Trials ongoing
mABs	Growth factors, growth factor receptors, cell surface antigens	Examples are trastuzumab for breast cancer, cetuximab for colorectal cancer
Modified peptides or biologic response modifiers	Circulating proteins, cell surface antigens, intra and extracellular proteins	Somatostatin analogues denileukin diftitox used to treat CD25 expressing recurrent CTCL
Small molecules	All of the above targets	Includes kinase inhibitors, proteosome inhibitors, matrix metalloprotease inhibitors, heat shock protein inhibitors and inhibitors targeting apoptosis

Therefore, choosing a targeted therapy is vitally important. Even if it is cytostatic in nature, it must be capable of causing either differentiation or prolonged growth suppression of tumor cells either as a single agent or as part of combination therapies. Developing rational combinations of targeted agents may also be more effective.

Simply put, cancer results as a consequence of oncogene protein activation or loss of tumor suppressor proteins. It is much easier to develop inhibitors of activated proteins than to replace suppressor proteins that have been lost (e.g., restoring the function of p53 or retinoblastoma proteins poses a significant technical challenge) [22]. However, other methods of using the phenomenon of loss of tumor suppressors have been developed. One such group of drugs are poly (ADP-ribose) polymerase (PARP) inhibitors, which produce synthetic lethality in breast cancer gene (BRCA)-mutated tumors [23].

At present, the proteins amenable to successful targeting are those activated by mutations, e.g., BCR-ABL, Eml-Alk4, EGFR, or those that are overexpressed or amplified, e.g., Her2, and are critical for the survival of malignant cells. The kinases are especially important in the pathways of cell growth, metabolism, migration, proliferation, and survival. Phosphorylation is a central process for pathway activation. Both kinases and phosphatases remove and add phosphate molecules, respectively, to the key functional proteins in these pathways [24]. Kinases therefore act as signal transducers and, when mutated, become attractive targets for inhibition of the tumor cell.

Usefulness of a targeted treatment depends on a number of factors

- Adequate delivery of the agent to the tumor cell
- Adequate binding of the agent to the tumor cell
- The presence of the agent within the tumor cell for sufficient time to produce a meaningful effect
- Unanticipated toxicities of the agent on the normal tissue—both acute and chronic
- Disadvantages of antibodies include large size and complex structure, making absorption difficult and the presence of alternate binding proteins in the blood and normal tissue, which may reduce the efficacy.

Validation of a target includes a number of important considerations

1. The particular gene and its target protein should be selectively expressed on the tumor tissue as compared to the normal tissue.
2. The protein should be essential for the survival, proliferation, and malignant behavior of the tumor cell.
3. Inhibition of the protein should lead to growth arrest or death of the malignant cell and produce the desired clinical effect.
4. The protein should not be expressed in the key normal tissues such as bone marrow progenitors, intestinal epithelium, heart, kidneys, and brain; otherwise, there would be significant toxicity.
5. The importance of the protein to be targeted in the functioning of normal cells should be elucidated before attempting clinical trials.
6. Most importantly, the availability of appropriate biomarkers for the targeted therapy is critical to identify responders that can further help in developing the drug in clinical trials.
7. Biomarkers can also help in optimizing the dose and schedule and also serve as surrogates for response (e.g., Her2 positivity in breast cancer treated with trastuzumab).

Table 4 Features shared by most small-molecule receptor tyrosine kinase inhibitors

Binding to the ATP site which may be an active or inactive conformation or even both
Usually inhibit more than one kinase but degree of selectivity varies
Oral treatments where half lives allow daily or twice daily dosing
Acceptable toxicities at clinically effective doses (Good Therapeutic Index)
Most are cytochrome P450 substrates therefore drug interactions and pharmacogenomics is important
Major side effects seen are due to the predominant protein inhibited EG skin toxicity with EGFR inhibitors

Perhaps the most attractive and well-studied targets are the growth factor receptors, many of which are receptor tyrosine kinases. These receptors are often overexpressed in malignant cells. In others, they appear to be mutationally activated. Their presence on the cell surface also makes them easily accessible for inhibition by antibodies and by small-molecule kinase inhibitors. Growth factors normally bind to these receptors on tumor cells and promote the tumor's metastatic potential. Receptor tyrosine kinase inhibitors share a number of features, which are listed in Table 4.

Signals from growth factor receptors travel downstream though multiple switches, activating a host of pathways, which ultimately reach cytoplasmic and nuclear effectors. The Ras and the phosphoinositide 3-kinase (PI3K) pathways are among the most extensively evaluated, and a host of actual and potential targets have been developed and identified, respectively. Figure 5 shows both these pathways.

Molecular targeted therapy is now part of standard anticancer treatment. Most of these inhibit the target directly, although the newer antibody drug conjugates (ADCs) deliver the cytotoxic drug directly into the tumor cell. Monoclonal antibodies have been approved for solid tumors such as breast, colorectal, lung, head and neck cancers, renal cell carcinoma, ovarian cancer and glioblastoma, and hematological malignancies like acute myeloid leukemia (AML), B-cell chronic lymphocytic leukemia (B-CLL), non-Hodgkin's lymphoma, and others. Receptor tyrosine kinase inhibitors are available for a number of targets, including BCR-ABL, C-KIT, platelet-derived growth factor receptor (PDGFR), EGFR, Her2, and vascular endothelial growth factor receptor (VEGFR).

This is an exciting period for targeted therapies, and the list of agents is likely to grow exponentially over the next decade. An improved understanding of the mechanisms of resistance of these agents and the development of combinations of targeted drugs are likely to increase the efficacy of these agents in the clinic.

8 The Principles of Cancer Immunotherapy

Cancer immunotherapy has developed very rapidly since 2010, although its development has a long history. In fact, the Nobel Prize for medicine in 2018 was jointly awarded to James P. Allison and Tasuku Honjo "for their discovery of cancer therapy by inhibition of negative immune regulation" [25, 26]. The goal of this treatment is to kill cancer cells by reactivating the immune system.

8.1 The Immune System

Our immune system is a complex one with both innate and adaptive systems. The innate system involves neutrophils and natural killer cells, whereas the adaptive system contains B cells, which produce antibodies and lymphocytes that consist of CD4 helper cells, CD8 killer cells, and forkhead box P3+ (FOXP3+) regulatory T cells. This adaptive system, which fights viral infections, also has the ability to control and eliminate cancer cells. Adaptive immune cells recognize foreign cells in the body by antigen presentation.

8.2 Antigen Presentation and Recognition

T-cell receptors found on the surface of B or T lymphocytes recognize the cancer cell, when the major histocompatibility complex (MHC) presents a small peptide fragment of the cancer protein to the lymphocytes. This is called antigen presentation. The final outcome of antigen presentation and recognition depends on the balance achieved by the costimulatory molecules or immune checkpoints on the target cancer cell and the lymphocyte. This is a highly delicate balance, and, if the signals are positive, then the immune cells get primed to attack the antigen or, in this case, the cancer cell. If, on the other hand, they are negative, then the antigen is accepted as normal and the immune system is inactivated. The immune checkpoints, which are relevant to cancer, include CTLA4, PD1 PD-L1.

8.3 Immunoevasion

The fact that a cancer becomes clinically detectable implies that it has evaded the immune system. This is known as immunoevasion [27]. During the growth of a tumor, cancer cells produce several aberrant proteins called "neoantigens," which can be recognized, as mentioned earlier, by antigen presentation. Our immune system therefore has many opportunities to eliminate the tumor, and this is referred to as immunosurveillance [28]. In other cases, the cancer cells and the immune system reach some sort of equilibrium and coexist. If for any reason, this balance gets disturbed and there is immunosuppression due to old age or other illnesses, then cancer cells escape the immune system and start to grow.

Immunotherapy for cancer aims at restoring immunosurveillance and getting rid of the cancer cells.

8.4 Cancer Immunotherapy

Cancer immunotherapy can be categorized as follows

- It can be active where it actively stimulates the immune system or passive where it simply alters immune signaling.
- The treatment can be specific, acting against a known target or antigen, or nonspecific, where the immune system is stimulated in general.

Figure 6 shows the types of immunotherapies available today. Some of these are discussed below:

Chimeric antigen receptor T (CAR-T) cells are a form of active nonspecific type of cancer immunotherapy that is increasingly being used and studied today. These T cells are derived from the patient (autologous) and genetically modified in vitro to express cancer recognition molecules on their surface. It is also referred to as adoptive cell therapy. Currently, CAR-T cells have been approved in the setting of relapsed adult NHL and childhood B-cell acute lymphocytic leukemia (B-ALL). Trials in the first-line setting are ongoing and in several other indications such as myeloma, AML, and even in some solid tumors like breast cancer. The major side effects are cytokine release syndrome and cytokine-related encephalopathy syndrome.

Humanized monoclonal antibodies have been available for over two decades now and are a prime example of passive specific immunotherapy. They cause death of cancer cells by direct actions, complement-dependent cytotoxicity (CDCC), and antigen-dependent cellular cytotoxicity (ADCC). Rituximab for lymphomas and trastuzumab for breast cancer are perhaps the most familiar and the most used antibodies in cancer treatment.

Immune checkpoint inhibitors are also a type of passive specific immunotherapy. Immune checkpoints play a key role in immunoevasion as discussed earlier, and inhibition of these checkpoints can restore immunosurveillance, thereby eliminating the cancer cells. These molecules are increasingly being used in the clinic, either alone or in combination with chemotherapy, and have been approved for over 10 solid tumors. Many more are in clinical trials.

The focus has been on the negative regulatory molecules in order to control immune checkpoint signaling. The mechanism of action of immune checkpoint inhibitors is relatively

	Non-specific	specific
Active	Bacillus Calmette-Guerin (BCG) Cytokines Oncolytic viruses	Cancer vaccines Oncogenic virus vaccines CAR-T-cells
Passive	Lymphokine-activated killer cells Tumour-infiltrating lymphocytes (TILS)	Monoclonal antibodies Radioimmunotherapy Ex vivo expanded antigen-specific T-cells Immune checkpoint inhibitors

Fig. 6 Types of immunotherapies available. [Adapted from Davis et al. [29]]

straightforward. As long as the immune system is in balance, there is no change. In case the tumor cell increases checkpoint signaling by increasing CTLA4 and PDL1, then the immune system gets inhibited. This is often the situation in metastatic tumors. By blocking the antibodies (CTLA4 and PD1/PD-L1) that block this signaling, this balance can be restored and the immune system can regain control of the cancer.

Important considerations when using immune checkpoint inhibitors to treat patients are as follows

- Checkpoint inhibitors only help some patients—only a minority of patients reap dramatic and enduring benefits from this treatment, and this is important for both the clinician and patient to keep in mind during treatment.
- Benefits from checkpoint inhibitors take long to occur—sometimes many months. Similarly, the side effects are also long drawn out. In fact, some patients experience a pseudoprogression after 6–8 weeks of treatment, and, if the patient is clinically well with imaging indicating progression, it is worthwhile to wait a further 8 weeks and continue treatment before prematurely stopping it.
- Disease stabilization is more common than actual shrinkage of the tumor, and this is indeed a reasonable end point while treating metastatic disease. Patients can live with disease stabilization for longer and with a good quality of life.
- Many cancers do not respond to checkpoint inhibitors for reasons that are not clear.

  Melanomas, lung cancers, renal and bladder cancers seem to respond to this treatment. However, prostate cancer and most breast cancers, ovarian cancers, and colorectal tumors do not respond.
- The side effects of checkpoint inhibitors result from immune overactivation. The common side effects are gastrointestinal, dermatological, and endocrine. In fact, any illness in a patient being treated with immune checkpoint inhibitors should be considered as autoimmune unless proved otherwise. They are slow in onset and slow to recover. Treatment consists of supportive care and immunosuppression.
- Patients on checkpoint inhibitors must continue to receive good palliative care as responses are rare and patients will continue to progress and die from the disease.

To summarize, we have looked at different systemic therapies for cancer and the principles that govern their use. The treatment of cancer is continuously evolving. Now, we have not only chemotherapy and hormonal treatments in our armamentarium but also a host of targeted therapies and immunotherapies. It is likely that a combination of two or more types of systemic therapies will prove more successful than using them alone. Further research and study are warranted to develop new and effective combinations for our patients in the clinic.

1 Introduction

Childhood cancers are extremely rare compared to those of the adult population, with approximately 300,000 children diagnosed worldwide with cancers annually in the 0–19-year age group [1, 2]. These represent less than 1% of all cancers in developed countries, but, in developing countries with a higher proportion of children, the incidence can be five times higher [2]. The incidence of cancer rates in children is steadily increasing over the years, with reported rates in 0–14-year-olds showing a jump from 124 per million person years in the 1980s to 140.6 per million person years in 2001–2010 [1]. With increasing implementation of programs aimed at detection, treatment, and surveillance of infectious and many non-infectious diseases, cancer has emerged as one of the leading causes of death in children and adolescents around the world with an estimated 80,000 cancer-related deaths in children per year worldwide. The disparities evident in the incidence and patterns of childhood cancers across high-income countries (HICs) and low- and middle-income countries (LMICs) extend to cure rates as well, with 80% of children with cancer cured of disease in HICs compared to 20% in LMICs [3]. The stark inequalities seen in both survival and mortality across these countries are palpable in the financial allocation for cancer care also, with only 5% of the global resources for cancer care invested in LMICs [4]. The trends in incidence, mortality, and patterns of childhood cancers are mostly obtained from cancer registries, which are an indispensable source of information to inform policies addressing childhood cancer control and also to assess the impact of such efforts.

Pediatric cancers differ from those in adults on various fronts ranging from biology, patterns of spread, histology, response to treatment, late effects, and cure rate. Unlike adult cancers, most pediatric cancers are not caused by modifiable risk factors. Moreover, children have less comorbidities compared to adults, but the developing organ systems, which are immaturely functional at earlier ages, present a distinct set of complications related to treatment, both acute and chronic. The increased responsiveness of most childhood cancers to therapy, which stems from the fact that the majority of pediatric cancers are "embryonal" in nature, translates to improved cure rates with timely diagnosis and treatment compared to adult cancers. Nevertheless, treatment of pediatric cancers warrants specialized diagnostic and treatment facilities, which can handle the specific complications anticipated in children. This chapter will provide a general overview of pediatric cancers and the epidemiology and

challenges in the management of pediatric cancers in resource-constrained areas.

2 Epidemiology of Childhood Cancers in the World

With nearly 90% of the world's children residing in LMICs, they constitute the major proportion of childhood cancers, nearly 84% [5]. However, global estimates regarding the incidence of cancers demonstrate a striking gap in the data available from HICs and LMICs, as evident from following registry-based analyses, which reveal that only 5–12% of LMICs are covered in these datasets: International Incidence of Childhood Cancer (IICC-3) [1], CONCORD-3 [6], GLOBOCAN 2012 [7], and Global Burden of Disease (GBD) 2016 studies [8]. The above studies represent the four most comprehensive sources for estimates of childhood cancer incidence, survival, and mortality from data published between 2000 and 2018. In addition to this, estimates of cancer incidence and survival based on population-based data from the United States are available from the Surveillance, Epidemiology, and End Results (SEER) program coordinated by the National Cancer Institute (NCI) [9]. These global, regional, and national estimates of the incidence, patterns, survival, and mortality are essential inputs to inform health policy decisions to design, implement, expand, strengthen, and disseminate various health-care services and evaluate the impact of the above decisions. Their role in etiological research and in improving outcomes cannot be understated.

2.1 Published Estimates of Global Cancer Burden

The published estimates of cancer incidence, survival, prevalence, and mortality based on four major research programs are summarized in the following Table 1 [10].

The global estimates of new cases and cancer deaths in children (0–14 years) in 2012 as per GLOBOCAN 2012 and GBD 2016 are presented in Table 2 [10].

The International Agency for Research on Cancer (IARC) has made estimates of childhood cancer incidence by world region and cancer type for the year 2018 for Lancet

Table 1 A summary of the four major published studies estimating childhood cancer incidence, survival, prevalence, and mortality [9]

	IICC-3	GLOBOCAN 2012	GBD 2016	CONCORD-3

Epithelial tumors and melanoma	5.1	4.7–5.5	10,332
Others and unspecified	1.1	0.9–1.2	1977

Commission, which are detailed in Tables 3 and 4, respectively [11].

These published studies have minimal data from LMICs with severe underestimation of the actual global burden of childhood cancers. It is estimated that 44% of all children with cancer globally remain undiagnosed and underreported due to barriers in access to health care with >50% underreporting in LMICs [11]. Underdiagnosis (due to poor access to diagnostics and health care), underregistration (due to underdiagnosis, inadequate capacity resources, and underreporting), poor quality of the registered data, different formats and coding systems, passive follow-up of registered patients for survival data (especially when registries are linked only to official public record systems like the death registration system, social and health insurance, electoral registers, or hospital records, which are inefficient or difficult to access), underregistration of privately treated patients, and noninclusion of all childhood tumors, especially solid tumors, are among the reasons for this underestimation of various indices.

2.2 Surveillance, Epidemiology, and End Results (SEER) Data

Approximately 16,400 children and adolescents <20 years of age are diagnosed annually in the United States corresponding to an age-adjusted incidence rate for all cancers of 15.8 cases per 100,000 person years for children (0–14 years) and 21.7 per 100,000 person years for adolescents (15–19 years) with 1300 and 600 cancer-related deaths in 2010 in the <15 year and 15–19 year cohorts, respectively.

In children aged 0–14 years, acute lymphoblastic leukemia (ALL) was the most common cancer (25.4%), followed by tumors of the central nervous system (CNS), primarily brain tumors (20.6%). The most common non-CNS solid tumor was neuroblastoma (7.0%), followed by Wilms tumor (5.4%). The remaining were non-Hodgkin's lymphoma (NHL) (5.9%), acute myeloid leukemia (AML) (5.0%), and other cancers like Hodgkin's lymphoma, rhabdomyosarcoma, nonrhabdomyosarcoma soft tissue sarcomas, germ cell tumors, retinoblastoma, and osteosarcoma constituting 2–4% each. In the 15–19-year-old group, Hodgkin's lymphoma (16.0%) and germ cell tumors (13.7%) were the most common followed by CNS tumors (9.7%). Non-Hodgkin's lymphoma (8.0%), melanoma (7.0%), thyroid cancer (8.7%), nonrhabdomyosarcoma soft tissue sarcoma (6.0%), osteosarcoma (4.1%), and Ewing sarcoma (2.0%) were seen in a higher proportion, whereas certain other cancers like rhabdomyosarcoma (1.7%), neuroblastoma (0.3%), and Wilms tumor (0.2%) are seen at extremely low rates compared to the 0–14-year-old age group [9].

Male preponderance for ALL, Hodgkin's lymphoma, NHL, retinoblastoma, hepatoblastoma, Ewing sarcoma, rhabdomyosarcoma, and nasopharyngeal carcinoma were seen in the 0–14-year age group with female preponderance observed for thyroid cancer in this age group. There were a few differences from the above noted in the 15–19-year-old age group with equal distribution of Hodgkin's lymphoma in both sexes, male predominance in germ cell tumors and osteosarcoma, and female predominance in Wilms tumor and melanoma.

2.3 Estimates of Global Childhood Cancer Survival

CONCORD-3 covered the 5-year net survival (the cumulative probability of surviving up to 5 years after diagnosis, after correcting for other causes of death) for acute lymphocytic leukemia, lymphoma, and CNS tumors during the period 2000–2014 for the 0–14 year age group but had only 5% representation from LMICs. The 5-year net survival for the United States based on this for various diseases were as follows: acute lymphoblastic leukemia and lymphoma- 89.6% [95% confidence interval (95% CI): 88.8–90.3%], acute myeloid leukemia- 67% (95% CI: 64.4–69.6%), Hodgkin's lymphoma- 100%, non-Hodgkin's lymphoma- 90.4% (95% CI: 88.6–92.2%), ependymoma and choroid plexus tumors- 84.2% (95% CI: 81.2–87.2%), astrocytoma-82.7% (95% CI: 81.3–84%), embryonal brain tumors- 69.4% (95% CI: 66.4–72.4%), other gliomas- 58.2% (95% CI: 55.4–60.9%).

A survival module to model the 5-year net survival for childhood cancers for 200 countries worldwide was developed to provide a comprehensive estimate of global childhood cancer survival, which was lacking for many LMICs [11, 12]. In 2015–2019, the global 5-year net survival was 37.4% [95% uncertainty interval (95% UI): 34.7–39.8%], ranging from 11.6% (95% UI: 8.7–14.8%) in Africa to 39.6% (95% UI: 35.1–43.6%) in Asia, 55% (95% UI: 51.2–58.7%) in Latin America and the Caribbean, 64.4% (95% UI: 58.9–69.2%) in Oceania, 74.3% (95% UI: 71.9–76.4%) in Europe, and 83.0% (95% UI: 81.6–84.4%) in North America. The modeled estimate of the 5-year net survival was only 7.4% (95% UI: 5–10.7%) in low-income countries but 79.8% (95% UI: 8.7–80.8%) in high-income countries, highlighting the striking gap across these countries.

3 Epidemiology of Childhood Cancers in India

3.1 Estimates of Incidence and Patterns

In India, cancer is the ninth commonest cause for death in children aged 5–14 years compared to developed nations where cancer is the leading cause of disease-related death in this age group [5, 13]. Merely 2% of all deaths in the pediatric age group are due to cancer in India compared to England and Wales where cancer contributes 20% to disease-related death in children, second only to accidents and injuries (21%) [14]. The National Cancer Registry Program (NCRP), run by the Indian Council of Medical Research (ICMR) covering population-based cancer registries (PBCRs), is the source of incidence and patterns of childhood cancers in India. The latest report (2016) covers <10% of country's population and provides data from 30 PBCRs, though with disparities in rural and regional representation [13]. This report shows a rise in childhood cancer incidence from 38–124 per million (pm) children in 2001–2004 and 11.3–159.6 pm in 2009–2011 to 6–860 pm in 2011–2014. Interestingly, childhood cancers showed a marginal reduction relative to cancers in all age groups in the same time periods (3.2% in 2001–2004, 3.1% in 2009–2014, and 2.5% in 2011–2014). The regional estimates of childhood cancer incidence in India are provided in Table 5.

In the NCRP report, males had a higher incidence (4–551 pm) compared to females (2–309 pm) with a male-to-female ratio of 1.6:1, slightly higher than that in the developed world with a ratio of 1.2:1 [2]. The highest incidence of childhood cancers overall and in males separately was seen in the 0–4-year age group, whereas females had the highest incidence in the 10–14-year age group. The relative proportion of childhood cancers in boys was the lowest in the Nagaland PBCR (northeast region) (0.7%) and the highest in the Delhi PBCR (north region) (5.4%), and, in girls, it varied from 0.5% in the East Khasi Hill district PBCR (northeast region) to 3.5% in the Naharlagun excluding Papum Pare PBCR (northeast region). The predominant childhood cancer was leukemia, with 70% being lymphoid leukemia. The second most common was lymphomas followed by CNS tumors, a reversal of what is seen in the developed world. Among lymphomas, NHL was slightly (54%) higher than Hodgkin's lymphoma, similar to the developed world, though an earlier review showed the reverse [15]. Leukemias, lymphomas, and CNS tumors had the highest incidence among the 0–4 year, 10–14 year, and 5–9 year age groups, respectively. Genitourinary, eye, and liver tumors were the highest among the 0–4-year age group and bone tumors among the 10–14 year age groups. The incidence of common cancer types in children is detailed in Table 6.

Table 5 Childhood cancer incidence in India as per location of the registry [13]

Registry location	Cancer incidence AAR per million (% of childhood cancers out of all cancers)		
	Boys	Girls	Total
National data	4–551 (0.7–5.4)	2–309 (0.5–3.5)	6–860 (0.7–4.4)
North	69–551 (2.4–5.4)	41–309 (1.3–3.2)	110–860 (1.8–4.4)
South	102–158 (1.8–2.9)	82–108 (1.3–1.5)	184–240 (1.5–2.4)
East	30 (1.1)	29 (1.1)	59 (1.1)
West	12–156 (2–4.5)	12–89 (0.9–2.5)	24–245 (1.5–3.4)
Central	44–65 (2.6–2.9)	26–47 (1.5–1.9)	70–112 (2.4–2.6)
Northeast	4–71 (0.7–3.3)	2–51 (0.5–3.5)	6–116 (0.7–2.7)

Age-adjusted rates (AARs) for 11 selected broad types of childhood cancers [leukemias, lymphomas, central nervous system (CNS) tumors, sympathetic nervous system (SNS) tumors, retinoblastoma, renal tumors, hepatic tumors, bone tumors, soft tissue sarcomas, germ cell tumors, and others]

3.2 Estimates of Cancer-related Mortality and Survival in India

PBCR survival data for childhood cancers have been reported from Bangalore and Chennai where the 5-year overall survival for all childhood cancers combined is 37–40% [15]. Hodgkin's lymphoma and Wilms tumor had the highest survival with approximately two-thirds of the children surviving for 5 years or more. The survival for retinoblastoma and germ cell tumors was less than that of the developed world. The prognoses for CNS tumors and leukemias were also low, with the 5-year survival rates being 25% and 33%, respectively. A higher survival rate is seen in those treated at specialized cancer treatment centers. In India, the mortality rate (adjusted to world standard population) varies from 14 to 34

Table 6 Incidence of common types of cancers in children in India in AAR per million children [13]

Diseases	Age group (years)						Total incidence
	0–4		5–9		10–14		
	Male	Female	Male	Female	Male	Female	
Leukemia	33.0	17.9	28.5	15.3	23.3	13.3	131.3
Lymphoid	25.7	13.0	19.6	11.0	15.9	6.9	92.1
Myeloid	5.1	3.2	6.7	3.2	5.0	5.3	28.5
Unspecified	22.2	1.7	2.2	1.1	2.4	1.1	10.7
Lymphoma	2.8	1.9	10.8	3.4	13.0	4.9	37.8
Non-Hodgkin's lymphoma	2.3	1.4	4.8	2.1	7.2	2.7	20.5
Hodgkin's lymphoma	2.5	0.5	6.0	1.3	5.8	2.2	17.3
CNS tumors	5.5	4.4	8.7	6.5	7.9	4.7	37.7
Genitourinary tumors	8.	5.1	2.0	2.5	1.6	5.2	24.8
Bone tumors	2.6	1.7	3.5	2.7	7.7	6.2	24.4
Eye tumors	7.7	5.1	1.8	0.5	0.1	0.3	15.5
Gastrointestinal tumors	0.5	1.0	1.6	0.8	1.8	1.0	6.7
Liver tumors	2.9	1.5	0.6	0.3	0.3	0.1	5.7

per million children per year, but, when the incidence of cancer is factored into this calculation (as incidence rates are low in some parts of the country), values depicted as the mortality incidence (M:I) ratio rather than mortality rates provide more clarity. The M:I ratio varies from 17 to 72% in India as compared to 20 to 24% in the United States and Britain [2]. The largest contributor to mortality in Britain is CNS tumors, but, in India, leukemia is the major contributor to cancer-related mortality.

In a study designed to procure direct estimates of childhood cancer mortality in India by enhanced verbal autopsies on a cohort of >27,000 pediatric deaths examined as part of the Million Death study, a mortality rate of 37% (95% CI: 31–42) per million population per year was obtained. This was more than many prior estimates of mortality. Disparities between mortality estimates were the widest in northeast India and for brain tumors [16]. Pediatric oncology in India still needs concerted, collaborative, and multidimensional efforts to reach international standards.

4 Challenges in the Management of Childhood Cancers in LMICs

The improvement in survival in pediatric cancers has been a paradigm where scientific advances in diagnosis, treatment, and supportive care have improved survival rates in many cancers; for example, in the UK, from <5% for childhood leukemias in the early 1980s to 80% by 1996–2000 [17]. The benefits obtained from these advances, resulting in remarkable improvements in survival in developed nations, have not translated into the same in LMICs with no narrowing of survival gap over time. Many factors contribute to the differences in outcomes, ranging from accessibility, availability, and acceptability of diagnostics and services to the advanced stage at presentation in resource-constrained areas. With the emergence of new evidence and collaborations worldwide, efforts to bridge this gap have been initiated aimed at delivery of cost-effective and adapted interventions with a tiered approach, identifying health delivery platforms of varying capabilities (primary health-care centers, district hospitals, specialist and teaching hospitals) to implement the varying intensities of treatment. The following are the main challenges faced in the treatment of childhood cancers in resource-constrained settings [11]:

Underdiagnosis The nonspecific manifestations of childhood cancers, especially hematolymphoid malignancies like leukemias and lymphomas, which can mimic infectious processes coupled with inadequate access to health-care delivery services, limited infrastructure, training, manpower resources, and service delivery networks, hamper the diagnosis of these malignancies. These limitations in diagnostic technology affect the diagnosis of childhood solid tumors far more, resulting in gross underdiagnosis.

Missed Diagnosis and Delayed Diagnosis The limitations as detailed above also contribute to missed diagnosis and delay in diagnosis, thereby hampering the timely delivery of treatment and affecting outcomes.

Inadequate Health-Care Infrastructure and Access to the Same There is a glaring deficit in the infrastructure needed to deliver proper and adequate services starting from the health delivery platforms available in LMICs. Childhood cancers require specialized diagnostic and treatment facilities, which also have the potential to take care of the anticipated specific complications in this vulnerable cohort. There is a lack of buildings, trained personnel (both medical and nonmedical), diagnostic modalities (including laboratory services, trained pathology, imaging services), and therapeutic services (chemotherapy, radiotherapy, surgery). Many sub-Saharan African countries lack any radiation unit; other countries have one unit per five million people, which restricts the delivery of one of the important treatment modalities for cancer [18]. The quality of chemotherapy drugs and their sustained availability is an issue in the continued delivery of care.

Lack of Supportive Care The paucity of sufficient supportive care networks, mainly addressing infection control and nutrition, precludes the use of the latest and best curative treatments in LMICs. Administration of chemotherapy with its attendant myelosuppression and infections can lead to increased morbidity and mortality in resource-constrained settings.

Dearth of Blood Products and Transfusion Support The successful treatment of childhood cancers, especially hematolymphoid cancers that constitute the bulk, requires a concrete transfusion support program, adequate number of blood donors and blood product units, and safety from transmissible diseases. A high seroprevalence of human immunodeficiency virus (HIV) and hepatitis B, especially in LMICs, reaching 10–25% among blood donors in Africa, warrants a hemovigilance system to monitor and improve the safety of transfusions [19]. Only 13% of LMICs have a national hemovigilance system, and only 53% of blood donations are appropriately screened [11, 20].

Malnutrition The prevalence of malnutrition is extremely high in LMICs, reaching 50–70% in some regions, and is associated with the inability to deliver dose-appropriate treatment, treatment interruptions and delays, increased toxicities (infectious and otherwise), and decreased survival [19].

Financial Constraints The delivery of the best contemporary treatment protocols requires financial support, which is otherwise unaffordable to the uninsured, lower-socioeconomic strata. Out-of-the-pocket expenditures, in addition to the treatment costs, incur additional financial burden on these families, as many of these health-care services are available at regions distant to their native places.

Treatment Refusal and Abandonment This is a real and concerning issue in many LMICs and is one of the major causes of treatment failure. The reasons for abandonment are multifactorial, with financial, social, and cultural causes. In an online survey conducted to assess the global frequency burden of this problem, 23,854 (15%) of 155,088 children, who were <15-years-old and newly diagnosed with cancer annually, were found to abandon therapy [21]. Approximately two-thirds of LMICs had median treatment abandonment ≥6%, but treatment abandonment ≥6% was reported in high- (9%), upper middle- (41%), lower middle- (80%), and low-income countries (90%, $p < 0.001$). Treatment abandonment may account for at least a third of the survival gap between HICs and LMICs.

A holistic support system consisting of the hospital team, nongovernmental organizations (NGOs), and governmental organizations along with a prospective tracking system were instrumental in reducing abandonment in a resource-constrained setting at the pediatric oncology department of Tata Memorial Hospital [22]. The annual rate of abandonment was reduced from 20% to around 5% [22] with these interventions.

Belief in Traditional and Complimentary Medicines Traditional healers have an increasingly recognized role in the communities in LMICs where the cultural beliefs and dependence on these medicines alone can lead to a delay in the diagnosis and treatment of curable cancers. A systematic review performed by the traditional and complimentary medicine Collaborative of the SIOP found that its median use during childhood cancer care is significantly higher in LMICs (66.7% ± 19%) compared with HICs (47.2% ± 20%), ($p = 0.02$) [23, 24]. The simultaneous undisclosed use of these medicines along with allopathic treatment can have hazardous consequences due to drug interactions and toxicities.

Lack of Palliative and Survivorship Care Palliative care is a core component of health systems, especially cancer care, which is lacking or underpowered in many LMICs. In LMICs, pain management is available in <50% of pediatric oncology units and high-potency opiates and adjuvant medications are available in <15% of these countries [25].

Moving forward, bridging the survival gap and addressing the above issues is being contemplated and is initiated by many committed stakeholders, and this collective engagement would go a long way in improving childhood cancer care and outcomes in LMICs. The World Health Organization (WHO) Global Initiative for Childhood Cancer was announced in 2018 with the aim of attaining 60% 5-year overall survival for children with the six most common childhood cancers globally by 2030, by providing governments with a technical package to scale up capacities and to expand and sustain them with support from global partners [26]. This is a key development in ironing out the inequity in health-care services across the globe and is a major drive toward attainment of WHO's Sustainable Development Goal (SDG) target of 3.4, which is to reduce premature mortality from noncommunicable diseases by one-third by 2030 [27].

Some of the steps put forward and implemented to scale up the childhood cancer services are detailed below [11]:

Tiered Health Service Delivery, Capacity Building, and Intervention Packages Identifying health delivery platforms (primary health centers, community health centers, district hospitals, specialist hospitals), strengthening health care in these systems, and integration of childhood cancer care into national health programs are the essential initial steps. A trained multidisciplinary medical and nonmedical workforce can be recruited in centers with varying capabilities such that satellite centers in greater numbers and better access to people in remote areas can deliver some aspects of treatment and supportive care, helping out families while dedicated higher-tier treatment centers, concentrated in resources and expertise, can deliver more complicated therapy. There should be increased access to medicines and technology and quality control to ensure the optimum continued delivery of treatment. The simultaneous integration of cancer care in essential benefits packages is the need of the hour to ensure equal benefits for all strata and to reduce abandonment.

Governance National cancer control programs and governing bodies should be developed and facilities and providers should be accredited.

Cancer Awareness There should be efforts to create awareness among the general public and general practitioners about the symptoms and diagnostic facilities available so that timely referral and treatment can be initiated. As a step toward this goal, the Pediatric Hematology Oncology (PHO) chapter of the Indian Academy of Pediatrics (IAP) initiated a National Training Program in Practical Pediatric Oncology (NTP-PPO) to train doctors, mainly in non-oncology centers.

Financing Both direct and indirect costs of treatment are an important deterrent to the initiation and continuation of therapy and hence should engage both the government and nongovernmental organizations and philanthropic support to ensure continued care and prevent abandonment. Government-supported health packages like the Ayushman health insurance scheme in India exemplifies this effort, thus limiting financial burden on the caregivers.

Twinning Programs Institutional and national collaborations open up opportunities for improvement in services, education, and research, and these exchanges have far-reaching consequences in improving outcomes on short- and long-term bases.

Health Information The development of cancer registries and inclusion of childhood cancers in them should be made mandatory, and these should be linked to regional and national databases of deaths to capture survival data. Vital statistical systems of the nations should also be strengthened as these data inform and guide the current and future policies.

Cost-Effective and Adaptive Treatments Local adaptation of treatment protocols must be done as per the evidence, to ensure maximum benefit with minimum morbidity and mortality due to treatment per se. This is important as most of the children in LMICs have additional issues like malnutrition in a setting where communicable diseases are also prevalent and are the competing causes of mortality in these immunosuppressed patients on therapy. There are some differences in the biology of various malignancies between HICs and LMICs, which could favor the adaptation of such cost-effective or less toxic protocols. Some examples of indigenously developed protocols adapted to the settings like MCP 842 for lymphomas, MCP841 for ALL (developed in collaboration with NCI, USA), EFT-2001 for Ewing sarcoma [28], and OGS 2012 for osteosarcoma [29] are relatively less toxic with good outcomes in resource-constrained countries. Metronomic chemotherapy with its attendant benefits of wide availability, limited costs, oral administration, and little infrastructure needs can be part of the constraint-adapted regimens in these resource-limited settings, with the understanding that metronomics shall not be a substitute for standard treatments wherever deliverable [30, 31].

In summary, effective delivery of childhood cancer care requires a comprehensive study of the current practices, incidence, and survival estimates to inform policies and to implement and scale up services in resource-constrained settings, thus warranting concerted efforts from different walks of the government, national and international institutions, and community as a whole.

Abbreviations

CSF	Cerebrospinal fluid
DCIS	Ductal carcinoma in situ
ER	Estrogen
FNA	Fine needle aspiration
FNAC	Fine needle aspiration cytology
FS	Frozen section
GMS	Gomori methenamine silver
H&E	Hematoxylin and eosin
HER2	Human epidermal growth factor receptor 2
IHC	Immunohistochemistry
IOC	Intraoperative consultation
ISH	In situ hybridization
LED	Light-emitting diode
LM	Light microscopy
LN	Lymph node
NBF	Neutral buffered formalin
NHL	Non-Hodgkin lymphoma
PAP	Papanicolaou stain
PAS	Periodic acid–Schiff
PR	Progesterone receptor
QA	Quality assurance
SOHD	Supraomohyoid neck dissection
SOP	Standard operating procedure
WSI	Whole slide imaging
ZN	Ziehl–Neelsen

1 Principles

The practice of surgical pathology primarily relies on an accurate and careful macroscopic gross examination of the excised tissue, followed by a more detailed histological examination of tissue sections, integrated with other relevant clinical details and ancillary techniques to arrive at a definitive diagnosis.

One of the primary challenges in cancer management is embarking on an accurate diagnosis in which the pathologist plays a pivotal role. A definitive diagnosis of any lesion identified clinically or radiologically rests solely on the histopathological assessment of the lesion. No matter how high the index of clinical suspicion is, the diagnosis of cancer is conclusively established only after a thorough histopathological examination, and, hence, the latter is considered as the gold standard.

Not many years ago was the time when a mere diagnosis of "benign" versus "malignant" was enough for patient management. That scenario is revamped now largely due to the central role of histopathological parameters and biomarker assessment in determining the therapy and the clinical outcomes. The task of a pathologist is to provide an accurate, comprehensive and an integrated diagnosis, elaborating the relevant points in terms of additional prognostic and predictive factors, apart from the traditional staging information of cancers. Even today, though histomorphology remains the key element in the tumour diagnosis, it is further supplemented by various ancillary techniques to provide additional prognostic and predictive aids. Now, the reality is that a histopathology report is the defining characteristic of not just the diagnosis, but, guiding the oncologists inpertinent patient management providing relevant prognostic and predictive information. This has eventually redesignated the role of "Pathologist" as a "Theranostic Oncologist."

In the past several decades, major innovation waves have impacted surgical pathological practice, gradually considering limitations of the morphology alone in cases with diagnostic dilemmas. First being the introduction of electron microscopy (EM) for ultrastructural study, which has provided an insight into the histogenesis of tumors and aided in the diagnostic workup of difficult neoplasms. Subsequently, immunohistochemistry (IHC), to study protein expression, gained tremendous response and has quickly become an

indispensable part of the surgical pathology practice, thus enabling finer subclassification, differentiating histological mimics and for various biomarker studies.

With the advent of high-throughput molecular techniques, there has been a revolutionary change in the cancer diagnostics as reflected in the constant characterization of previously unrecognized tumor types or variants. In many primary sites, tumor classification is now largely molecular -based, each with its own characteristic biology and behavior to allow the most appropriate classification for therapeutic intervention, to determine prognosis and for research. Details, viz., the tumor type, grade, differentiation, invasion parameters, proliferation index, pathological stage, metastatic status, hormone and other target receptors' status, etc., are often integrated with the molecular marker studiess.

Lastly, digital pathology with adoption of whole slide imaging (WSI) is deeply getting ingrained in histopathology, and artificial intelligence (AI)-powered applications are progressively getting incorporated in routine diagnostics.

In order to accomplish maximum information out of the tissue excised or biopsied, the specimen must be adequately fixed, grossed, processed, and stained to enable generation of the final histological report with a comprehensive diagnosis, which is clinically relevant and useful. In the subsequent sections, we will discuss the technical aspects, viz., grossing, tissue processing, staining, microscopy and other ancillary techniques pertaining to general oncopathological practice.

2 Grossing

The most important and basic step in surgical pathology is grossing. The interpretation of gross lesions begins with the observation, which indirectly serves as a road map to sampling representative areas for histological evaluation.

A correctly and adequately grossed specimen provides information related to the diagnosis, margin evaluation, nodal status, pathological staging, and residual tumor/posttreatment response evaluation.

2.1 Basic Requirements of Dissection/ Grossing Room

- A well-illuminated and adequately ventilated room with a powerful exhaust system to eliminate tissue odors and formalin vapors
- Grossing tables with boards with basic stationary and surgical instruments, viz., scalpel blades, forceps, scissors, knives and a scale, gloves, cotton, comfortable chairs, a formalin tank, and a water sink
- Bone saw for grossing bone specimens
- Leak-proof specimen containers, shelves, and compacters
- Disposal bins
- Photography facility
- A first aid box

2.2 Receiving Specimens

The samples are received safely and securely in the "specimen-receiving room." The main tasks to be accomplished in this room include the following:

- To match the identification mentioned on the requisition form and the specimen containers, confirm the number of specimens/ containers received, to check whether appropriate clinical details are mentioned, and to assign a unique laboratory specimen identifier number
- To note the condition of the specimen at the time of receiving it (if in inadequate formalin or autolyzed)
- In case of any doubt/discrepancy in the specimens received, the concerned/referring clinician should be contacted.
- The specimen may be rejected in case of any major discrepancy, the criteria for which should be clearly mentioned in the laboratory standard operating procedures (SOPs).

2.3 Specimen Fixation

Good and prompt fixation of the specimen is the prerequisite for surgical pathology. Cold ischemic time should be less than 1 h. In case of an anticipated delay of surgical specimens to reach the pathology laboratory for fixation, these can be kept in a refrigerator at 4°. Of the many fixatives available, 10% neutral buffered formalin (NBF) is the most preferred for routine histopathology, IHC, and molecular pathology techniques.

- Specimens should be adequately fixed, with the volume of the fixative being at least 10 times that of the tissue.
- Small biopsies are fixed immediately, for approximately 4–6 h, whereas for big specimens, at least 8–12 h are recommended. Over- or underfixation of a tissue has a deleterious effect on further downstream techniques.
- Big resection specimens are inked, serially sliced, and packed with formalin-soaked cotton in between the slices to facilitate persistent and optimum formalin penetration to prevent tissue autolysis.
- Gross photography is an integral part of surgical pathology and should be preferably performed when the specimen is in a fresh state, especially for rare and unusual cases.

2.4 Grossing/Surgical Cutup

2.4.1 Orientation of Specimens

Specimen orientation is important in oncopathology for surgical margin status evaluation, providing a guide to the surgeons to revise the close/positive margin/s in future.

- Apart from small biopsies and specimens, which can be oriented by anatomic locations, like colon specimens, a majority need to be oriented by the surgeons and mentioned accordingly on the requisition form.
- Most of the specimens are oriented with sutures, for example, in breast lumpectomy, a short suture is usually placed superiorly and a long one laterally. Sometimes, the lesion is marked with the guide wire after mammography guided localization, especially in post-chemotherapy settings.
- Revised margins are commonly oriented mostly as ink away from the tumor. Margins sampled should be always mentioned, if shave (S) or radial (R) margins are taken.
- Specimens, which are unoriented, should be mentioned in the gross findings. In such cases, the closest margin should be sampled.

2.4.2 The General Principles of Grossing

Before the actual start of tissue dissection, reconfirming the patient's identification, patient/specimen type, specimen orientation, and measurement is essential.

Information on specimen receiving, fixation, and grossing date and time, along with the names of the pathologist and the technician, should be mentioned on the surgical pathology form.

2.4.3 Gross Description

A thorough and meticulous examination of the specimen and sampling the appropriate areas form the basic premise of grossing. The description should be concise but precise.

- A gross description of the primary lesion should include its distribution, contour, color, shape, size, and consistency.
  - Distribution—unifocal, multifocal, or diffuse type of lesion
  - Contour—the relationship of the lesion with respect to the adjacent tissue and whether proliferative, infiltrative, or a flat lesion
  - Shape—ill-defined, circumscribed, or well-encapsulated
  - Apperance: Uniform/ variegated Necrosis - Present/ Absent Color—pale, brownish, hemorrhagic or blackish, pigmented
  - Consistency—soft, firm, or hard
  - Size—exactly three dimensions, with mention of the depth of invasion in cases with an infiltrative component
- The status of the adjacent tissue or any other secondary pathology, if present, should be mentioned.

2.4.4 Margin Evaluation

A surgical pathology report is incomplete without the mention of the status of the surgical margins.

There are two types of margins: shave face and radial/perpendicular. Shave margins have the advantage of being able to sample a larger area and are usually taken when the margins are grossly far away from the primary lesion (usually more than 1–2 cm away). However, the disadvantage seems to be higher chances of a false-positive margin, in cases with thick sections, and the inability to calculate the exact distance from the lesion microscopically.

On the other hand, radial margins, where a small portion of the tissue along with the lesion is sampled, prove useful in cases with close surgical margins for exact measurement of the microscopic distance of the margins from the lesion.

Usually, single black ink suffices if only one margin is sampled in one section. For cases with possible multiple margins in a single section, e.g., in Whipple's resection or vocal cordectomy specimen, different margins can be inked with different colors to facilitate their identification under microscopy.

2.5 Blocking Principles

2.5.1 Primary Lesion/Tumor

- A minimum of four sections from the main tumor, including sections with maximum depth and with an adjacent normal tissue. For certain tumors, like solid-cystic ovarian tumours, one section per centimeter of circumference is considered as optimum sampling.
- In case of an ill-defined lesion, additional sections may be submitted.
- In post-neoadjuvant treatment, the slice most representative of the tumor bed is submitted in a grid manner after matching with imaging.
- With multiples tumors, the intervening tissue is submitted.
- With large tumors with variegated appearance, multiple sections are submitted from grossly varied areas. Necrotic and hemorrhagic areas also need to be sampled.
- In solid cystic tumors, solid areas should be sampled adequately. In cystic tumour, areas with maximum cyst wall thickness should be sampled.

- Adequate evaluation of certain adjacent structures is critically important for pathological staging, e.g., skin involvement in breast tumors, pleura in lung resections, underlying bone in head and neck cancers, etc.

2.5.2 Margins

- All margins are labeled, mentioning the type of margin (radial or shave), and submitted separately one per block, with the inked surface guiding the embedding direction.

2.5.3 Adjacent Tissues

- Representative sections from the adjacent tissues should be submitted.

2.5.4 Lymph Nodes (LNs)

- All the lymph nodes, including those of the specimens as well as those sent separately, should be grossed and sampled entirely, unless it is grossly metastatic, wherein a single representative section is submitted.

2.5.5 Bone

- All the bony hard/calcified tissues should be decalcified using laboratory protocols before tissue processing.

3 Safety Precautions

All specimens must be considered a potential biohazard, and necessary universal safety precautions need to be followed with protective clothing, including good-quality masks, aprons, gloves, and goggles. Strict laboratory protocols need to be laid down and followed forthwith after the occurrence of any laboratory accident, e.g., sharp injuries, splash exposure, etc.

4 Staining

Following the series of tissue-processing steps, sections from the paraffin-embedded blocks are subjected to “staining.” This imparts color to an otherwise transparent tissue, thus enabling the pathologist to appreciate the morphological details under a microscope. It plays a crucial role in diagnostics and research settings.

The term “routine staining” in the histopathology laboratory refers to the conventional hematoxylin and eosin (H&E) stain, which is used for staining all tissue sections. Similarly, for cytological specimens, routine stains include Papanicolaou (PAP) stain, which is a combination of hematoxylin with Orange G 6 and eosin azure (EA) 50, whereas for hematological/bone marrow specimens, the most commonly used stains are Romanowsky stains (Wright and Giemsa stains). The term “special stains” refers to various other alternative stains that can be used as a diagnostic aid, in addition to routine staining to provide additional details. The term “advanced staining” refers to IHC or in situ hybridization (ISH), which stains the proteins and in situ DNA or RNA sequences, respectively.

4.1 Hematoxylin and Eosin (H&E) Staining

H&E staining is a basic and simple-to-use technique, which stains the nucleus and cytoplasm of a cell, including its extracellular components. This is the most frequently used stain in all the histopathology and some cytology laboratories for making a diagnosis, as it clearly highlights the underlying tissue morphology. The H&E stain has two dyes, which is a combination of hematoxylin, a basic dye (purplish-blue color, which stains acidic structures like the cell nucleus containing DNA and nucleoproteins as well as organelles that contain RNA, and eosin, an acidic dye (reddish or pink), which stains basic structures like the cytoplasm, cell wall, and extracellular matrix.

Automated staining machines and commercially prepared hematoxylin and eosin solutions are commonly used in modern laboratories for routine staining and form the most essential component of any histopathology laboratory.

4.2 Special Stains

Special stains include those that may be used to visualize specific tissue elements, or even microorganisms, which are not identified by H&E staining. In diagnostic pathology, common usage of special stains is now largely restricted to demonstration of organisms, viz., mycobacterium with Ziehl–Neelsen (ZN), fungus by Gomori methenamine silver (GMS) stain and periodic acid–Schiff (PAS) stain, and *Helicobacter Pylori* organisms with Warthin–Starry and Giemsa stains.

Traditionally, some of the special stains played a crucial role in diagnostic oncology, which have now largely been replaced by IHC. Some are still helpful adjuncts to tumor morphology, e.g., Fontana–Masson stain to demonstrate melanin pigment in a suspected case of malignant melanoma.

5 Frozen Section (FS)

Intraoperative consultation is a major responsibility of an oncopathologist and is considered as the most dynamic part of the practice. However, it is important to triage the specimens and not necessarily process them if there is no intent to modify the surgical procedure.

5.1 Basic Frozen Section (FS) Workflow

An unfixed tissue specimen reaches the FS station from the operation theatre accompanied by the requisition form mentioning the parameters that need to be assessed. The pathologist then grossly examines the specimen and submits representative sections for histological evaluation. These sections are then hardened by freezing in a cryostat (−20 to −30 °C), followed by sectioning (4–7-μm thickness), and subjecting them to staining. Rapid H&E staining and toluidine blue are the common stains used in FS. The approximate turnaround time is 20 min, from specimen receiving to the final FS diagnosis.

5.2 Indications

Broadly, the major indications for intraoperative FS that guide the surgical plan are

- Diagnostic
- Margin evaluation for the adequacy of surgical resection
- Lymph node (LN) status

5.3 Diagnostic

- To establish the nature of the lesion: benign vs. malignant
- To ascertain any clinically suspicious areas, which are unexpectedly encountered at the time of surgical exploration
- To evaluate the tumor grade, high- vs. low-grade, which determines the extent of surgery, e.g., for mucinous tumors of the colon
- Depth of invasion of the myometrial wall thickness
- To evaluate meticulously for any skip lesions in addition to the primary tumour mass in an excised specimen
- To determine the exact site of origin, primary versus metastatic in cases with multiple tumors

5.4 Margin Status

Adequacy of surgical margins is a pivotal prognostic and predictive parameter in big resection specimens in oncology, though the adequacy criteria differ and are based on the site affected.

It is necessary to mention the type of margin sampled (radial versus shave) and the exact microscopic distance of the tumor from the margin when close, even if the inked margin is technically free.

5.5 Lymph Node (LN) Status

LN status is one of the independent prognostic and predictive markers in oncology.

In breast carcinoma, sentinel LN status guides the axillary nodal dissection. In addition to the number of positive nodes, approximate nodal deposit size [if micrometastasis is (0.2–2 Mm) or macrometastasis is (>2 Mm)] and information on the extracapsular extension can be useful for making intraoperative decisions. Similarly, in head and neck cases, the nodal status of the contralateral side decides the level of neck dissection, supraomohyoid neck dissection, or modified neck dissection.

5.6 Frozen Artifacts and Limitations

Both the pathologist and the operating surgeon should be aware of certain limitations of the FS, which can lead to inaccurate diagnosis.

FS-related errors are classified as sampling, technical, or interpretative errors.

5.6.1 Sampling Errors

These errors are encountered due to inaccurate sampling carried out by the surgeon or grossing by the pathologists.

As in FS, most representative sampling is carried out and multiple sectioning is not feasible. This is especially important in encapsulated follicular neoplasms, wherein the malignancy criterion is capsular or vascular invasion, and in borderline ovarian neoplasms, wherein multiple sections are needed to rule out an invasive focus.

5.6.2 Technical Errors

As freezing is the medium of tissue hardening, a wide range of artifacts are commonly encountered, with the most common being tissue folds, improperly cut sections, especially of the fatty tissue, patchy and weak staining, and freezing artifacts obscuring the morphology, all of which can ultimately lead to diagnostic dilemma and interpretative errors.

5.6.3 Interpretative Errors

Poor differentiation of tumors, heterogeneity, varied and unusual morphologies and patterns, and sometimes crushing can lead to diagnostic difficulties, which need definitive characterization after paraffin processing and must be conveyed in the FS reports.

For a successful FS practice, knowing treatment algorithms with FS implications, effective communication, seeking a second opinion, and asking for an additional tissue, whenever required, would be a prudent approach.

6 Microscopic Techniques

A light microscope is the most essential part of a histopathology laboratory, which allows the microscopic evaluation of the target tissue at varying magnifications. The basic components of a light microscope include a light source, condensers, a body tube, an object stage, an objective, and an eyepiece.

The type and quality of the objective has the greatest influence on the microscope. Achromatic objectives are the most widely used for routine purposes. In most of the microscopes, the objective magnification powers range from 4× to 100× and the ocular magnification most commonly present is 10×. As a result, a standard microscope will provide a final magnification range of ~40×–1000×.

Depending upon the light path, transmitted light, or reflected light, different types of microscopic techniques exist, viz., bright-field, dark-field, phase contrast, interference microscopy, and polarized light microscopy.

The most commonly used technique is “bright-field” transmitted light microscopy for routine histopathological analysis of H&E, special stains, and IHC stains.

A polarizing microscope is a conventional microscope in which a polarizer and an analyzer is interposed and aligned, such that a birefringent object will appear bright against the dark background. This has many diagnostic applications in routine diagnosis, e.g., amyloid deposits in medullary carcinoma of the thyroid, etc.

Techniques dependent on the reflected light are fluorescence microscopy, confocal microscopy, and electron microscopy.

For fluorescence microscopy, different components like excitation, emission filters, a light source, a target tissue tagged with fluorophores, and a dichroic mirror are essential. It relies on the property of certain substances, which, when illuminated by light of a specific wavelength, will re-emit this light at a longer wavelength, which can then be visualized by the eyes. Fluorescence in situ hybridization (FISH) diagnostic tests make use of this technique.

Electron microscopy, although is diagnostic of certain neoplastic conditions, viz., demonstration of Birbeck granules in Langerhans cell histiocytosis, is not a preferred diagnostic modality due to the availability of superior and universal diagnostic techniques, viz., IHC. Moreover, the potential limitation of EM lies in the need for high cost of instrumentation, the level of technical expertise, and the stringent level of tissue processing. A confocal microscope is mainly utilized for research applications.

7 Cytology

The field of cytology has mainly two branches, viz., exfoliative cytology and fine needle aspiration cytology (FNAC).

Several factors play an important role in the evaluation of cytological specimens. The first and most important step is appropriate collection and handling of the specimens. Cancerous cells are often fragile, and, to identify these cells properly, they must be handled carefully during processing.

7.1 Types of Cytological Specimens

7.1.1 Exfoliative Cytology

Serous effusions, cerebrospinal fluid (CSF), urine, or samples that are forcibly removed, e.g., bronchial brushings, cervical, oral scraping smears

7.1.2 From a Lesion/Mass

Fine needle aspiration (FNA) and touch/imprint smears

7.1.3 Selection of Stains and Fixatives

The PAP stain is the most popular staining technique highlighting the crisp nuclear details. The most commonly used fixative is 95% ethyl alcohol.

The PAP stain slide should be combined with other stains like Giemsa and/or H&E, which highlight the cytoplasmic characteristics and are useful in highlighting various stromal features that are diagnostic of certain neoplasms.

7.2 Key Points in the Evaluation of Cytological Specimens

Before evaluating the cytological specimens, it is important to know how a cytological interpretation is different from an histological assessment. Especially in exfoliative cytology, abnormal cells are mainly discohesive with no stromal interface, a pattern-based approach to diagnosis is not always possible.

Smears are sometimes uneven, not with uniform thickness, with overlapping fragments, and enmeshed in the background material, thus leading to difficulty in evaluation. In addition, the relation of the lesion to the adjacent tissue cannot be ascertained in the cytological evaluation.

Scanty cellularity again poses diagnostic dilemmas, necessitating repeat evaluation in such cases.

7.3 Approach to Evaluation of Cytological Specimens

First and foremost, patient identification and rechecking the number mentioned on the requisition form and the smears should be performed.

A scanner view is used to assess cellularity and adequacy and then a low/high-power view is used for cytomorphological details, e.g., cell size, cellularity pattern, cell shape, nuclear features, cytoplasmic granularity, type of the stromal tissue and matrix, etc.

7.4 Cytology in Oncopathology: Interpretative Issues

Broadly, cytological assessment is helpful in oncological settings

- To identify and distinguish a benign tumor from a malignant one
- To further characterize the type of malignancy, such as carcinoma vs. lymphoma vs. sarcoma
- To differentiate high-grade from low-grade tumors, which is especially important in salivary gland tumors. To identify the metastatic nodal/ distant metastases

Although in majority of instances, cytological assessment helps in arriving at a definitive diagnosis, many scenarios do exist, which limits its diagnostic potential in cases, e.g., exact characterization of malignant small round cell tumors and further classification of differentiated thyroid follicular patterned neoplasms.

Nevertheless, ancillary techniques like IHC, EM, and molecular studies can be employed in such cases to aid in the final diagnosis. Moreover, cell block preparations from cytological specimens provide better material to perform various ancillary techniques over conventional smears.

8 Immunohistochemistry

IHC is based on the principle of antigen–antibody reaction for localizing specific antigens on cells in tissues. It has now become an important, valuable, and indispensable component of surgical oncopathological practice.

The first immunological method for diagnostic use was developed by Dr. Albert H. Coons in 1941, who officially launched the light microscopic (LM) IHC. However, only after the development of monoclonal antibodies in the late 1970s did the full-proof incorporation of IHC in pathology begin.

8.1 Applications

The applications of IHC can be classified further depending upon its utility as a diagnostic, prognostic, predictive, or genogenic marker.

8.2 Diagnostic

Usually, a panel of IHC markers are ordered, however, in an algorithmic manner

- Benign versus malignant lesions
- Classification of papillary lesions of the breast [papilloma versus papilloma with atypical features vs. papillary ductal carcinoma in situ (DCIS)] is largely dependent on the presence and absence of myoepithelial markers
- To differentiate prostatic carcinoma (especially if minute foci) from benign mimickers and precursor lesions
- Categorization of undifferentiated malignant tumors (carcinoma versus sarcoma versus lymphoma)
- Common scenario of soft tissue tumors
  - Malignant small round cell tumors (Ewing sarcoma versus Rhabdomyosarcoma versus Neuroblastoma versus poorly differentiated synovial sarcoma)
- Adenocarcinoma versus malignant mesothelioma
- To determine the primary site in cases with metastatic carcinoma
- Workup of hematolymphoid malignancy

8.3 Prognostic

- Hormone receptors [estrogen receptor (ER), progesterone receptor (PR), and human epidermal growth factor receptor 2 (HER2)] are prognostic markers in breast cancers.
- Tumors with a high proliferation index (Ki67) are high-grade and are associated with poor prognosis. In breast cancers, Ki67 is used as a surrogate marker for identifying luminal B subtype.

8.4 Predictive/Theranostic

The following are examples of biomarkers with predictive abilities

- ER/PR—Tamoxifen in breast cancer
- HER2—Anti-HER2; Trastuzumab in breast cancer
- CD20—Rituximab in B-cell NHL
- PD-L1—Immunotherapy

8.5 Genogenic

With so many molecular interventions in oncology, IHC is now increasingly being utilized to identify the underlying molecular abnormality, which further aids in diagnosis and guides patient management by identifying molecular therapeutic targets. This is a cost-effective and quick alternative to expensive molecular techniques.

- Identification of molecular alteration with the loss of IHC markers
  - Loss of integrase interactor 1 (INI-1) expression (surrogate for various molecular alterations affecting the INI-1 gene, including homozygous or heterozygous deletions, copy number alterations, epigenetic silencing, etc.) in SMARCB1 (INI-1)-deficient sinonasal tumor (diagnostic and prognostic)
- Identification of molecular alteration by the presence of protein expression
  - NUT protein expression (NUT gene rearrangement with BRD3 or BRD4) in NUT midline carcinoma (diagnostic and prognostic)
  - Anaplastic lymphoma kinase (ALK) protein expression (ALK gene rearrangement) in lung adenocarcinoma (predictive)
  - The presence of expression of the IDH-1 R132H mutation-specific antibody in gliomas (diagnostic and prognostic)
  - HER2 protein expression in >10% tumor cells with strong, intense, membarnaous staining pattern (HER2 gene amplification) in breast cancer (prognostic and predictive)

Although IHC has widespread applicability in the evaluation of tumors, its interpretation rests on clinical and morphological details and technical aspects. A well-preserved, fixed, and well-processed tissue is essential for optimal results of IHC. IHC does not work well with frozen and decalcified tissues and interpreting it as a true negative would be an error. Finally, it should be kept in mind that it is an adjunct to diagnosis and should be ordered and interpreted in an algorithmic pattern, considering possible clinical and morphological differential diagnoses.

9 Molecular Pathology

Molecular techniques represent a powerful strategy for screening, early detection (e.g., cancer of the cervix), tumor classification (e.g., breast cancer), monitoring efficacy of intervention, and unraveling disease mechanisms (e.g., hematolymphoid malignancies). Discoveries in our understanding of the molecular basis of disease are opening new avenues to new treatment modalities, as is evident from advances in the treatment of lung cancer. Molecular techniques, viz., polymerase chain reaction (PCR), sequencing, in situ hybridization, droplet digital PCR, and next-generation technologies in conjunction with advanced biochemical methods, innovative fluidics, and electronics, are employed to address the need for robust, automated test systems in contemporary molecular diagnostics.

Examples

- Fluorescent in situ hybridization (FISH) for in situ visualization of varied genomic alterations, including gene amplifications, gains, gene rearrangements, translocations, deletions, etc. This technique is utilized in wide range of solid tumors, including carcinomas, sarcomas, and lymphomas for diagnostic, prognostic, and therapeutic purposes.

9.1 Diagnostic

- Morphologically similar looking tumors in a spectrum of malignant small round cell tumors like Ewing sarcoma and poorly differentiated synovial sarcoma can be differentiated by demonstrating *EWSR1* gene rearrangement in Ewing sarcoma vs. *SSX18* gene rearrangement in synovial sarcoma.
- PCR-based clonality analysis and T- and B-cell gene rearrangement studies are helpful in distinguishing reactive lesions from lymphomas and further subtyping the lineage of lymphomas, whether B cells or T cells.

9.2 Predictive

Non-small cell lung carcinoma (NSCLC) with *ALK* gene and reactive oxygen species (*ROS*) gene rearrangements respond to the ALK and ROS TKI (tyrosine kinase inhibitors), respectively and breast cancers with HER2 gene amplifications respond to anti-HER2 agents.

Sanger sequencing is used to detect changes and alterations in the DNA sequence like, single nucleotide variants, point mutations, frameshift mutations like indels, complex mutations, etc. Gastrointestinal stromal tumor (GIST) patients with KIT exon 9 mutations receive 800 mg once a day (OD) of imatinib and patients with exon 11 mutations receive 400 mg OD. BRAF and MEK inhibitors targets tumours, like melanomas with a *BRAF V600E* substitution mutation.

9.3 Prognostic

A neuroblastoma with MYCN gene amplification connotes poor prognosis. Multiplex ligation-dependent probe amplification (MLPA) to study DNA copy number alterations is employed in neuroblastomas to demonstrate recurring genetic alterations affecting multiple chromosomes, including losses of the 1p, 3p, 4p, and 11q and/or gains of 1q, 2p, and 17q, which further supplement prognostic information, in addition to the MYCN status.

Next-generation sequencing testing is a massive, high-throughput parallel sequencing to detect copy number aberrations, single nucleotide variants, complex mutations, fusions, and the microsatellite instability status of multiple genes and encompasses an “all-in-one” test. This helps reduce the turnaround time in routine cancer management, e.g., in NSCLC cases.

10 Biorepository

With exponential developments in genomics and proteomics and greater emphasis on translational research, the need for human tissue samples to be used in translational research has grown. Therefore, safe and effective management of biospecimen banking services and biorepositories that store tissues for research use is the need of the hour. Contemporaneously, the ethical and regulatory environment for using human tissues in research has also become increasingly complex. Well-organized biorepositories that practice standardized methods for collection, long-term storage, retrieval, and distribution of specimens with sound ethical principles are an appropriate response to this situation, ensuring that the rights and interests of specimen donors/patients are protected and also that important research can proceed with high-quality, research-grade biospecimens. It provides a greater understanding of the disease and helps answer important questions about why cancer develops, how it grows, and who is at risk.

Large pathology departments located at tertiary cancer centers are in a vantage situation to establish bioresource centers by undertaking various tasks, e.g., operational, administrative, and legal/ethical tasks involved in the running of a successful biorepository.

11 Digital Pathology

Whole slide imaging (WSI), an emerging tool in diagnostic pathology, involves scanning of a glass slide and converting digital information into a virtual slide. WSI has been successfully utilized for primary diagnosis, secondary consultation (peer-to-peer case review or expert opinion), intraoperative consultations (FS diagnosis), remote diagnosis, quality assurance (QA), multidisciplinary interactions (e.g., tumor boards), and patient consultations.

The concerns limiting the regular usage of digital pathology (DP) in routine practice include the exorbitant cost of the setup, including high-quality slide scanners, high-resolution monitors, and data storage and security. The need for high-speed Internet connectivity cannot be underestimated in DP. However, with technological refinement, improvement in connectivity, and high-resolution imaging, pathologists have now gradually incorporated the usage of digital microscopy even for the purpose of primary diagnosis.

In a vast country like India, the utility of WSI can have an immense impact, wherein opinions can be sought by underprivileged centers with limited resources, manpower, and expertise from tertiary care institutions with better expertise.

11.1 Digital Pathology and Artificial Intelligence

Adoption of WSI and the resultant generation of digital histopathological images has led to the increased interest and demand for their analysis, such as computer-aided diagnosis using machine learning and deep learning techniques.

Powerful artificial intelligence algorithms with constellation of histopathological images, genomic data, and clinical/radiological data can be utilized to make predictions about the evolution of tumors and would allow treatment to be precise and personalized in its true sense.

1 Introduction

Modern hematopathology practice employs a systematic approach in order to render a diagnosis that is clinically appropriate, evidence-based, and serves as a guide toward personalized medicine. It involves careful morphological study of the peripheral blood, bone marrow aspirate, followed by classification of the neoplasm according to the immunophenotype. Finally, molecular testing is an integral part of the present-day test battery, as the World Health Organization (WHO) 2017 [1] classification mandates classifying neoplasms according to their recurring genetic abnormalities, to guide appropriate treatment. This chapter discusses the essential aspects of a hematopathology laboratory, specialized in hemato-oncology, an overview of the techniques used, and the applications in various hematolymphoid neoplasms.

2 Organization and Elements of a Hematopathology Laboratory

A hematopathology laboratory is comprised of different specialized sections, encompassing the various stages of sample processing and diagnosis. Once a sample is received, it undergoes a myriad of processing methods, which include the following in order:

2.1 Sample Processing

- **Slide preparation and staining**: Morphological evaluation of the bone marrow aspirate slides requires adequate slide preparation and staining with one of the Romanowsky stains (e.g., Wright, Giemsa, Leishman).
- **Processing for flow cytometric evaluation**: This includes different protocols like "lyze–stain (staining with the antibodies)–wash" or "stain–lyze–wash", including permeabilization for cytoplasmic markers.
- **Pre-PCR (polymerase chain reaction) processing for molecular tests**: First, the erythrocytes are lyzed and the nucleic acids—DNA and RNA—are extracted using manual or automated kit-based techniques.
- **PCR**: The template DNA extracted is exponentially amplified using specific primers. The RNA is reverse-transcribed to complementary DNA (cDNA) and then further processes are carried out. The various applications of PCR are discussed in detail in the section "Molecular techniques."
- **Library preparation for next-generation sequencing (NGS)**: Library preparation is the single most important component of a next-generation sequencing test. Adequate amplification and target enrichment with addition of unique molecular barcodes are important basic steps for the same.

2.2 Analysis

- **Morphological evaluation**: Specialist hematopathologists perform careful morphological analysis of the bone marrow aspirate slides, which involves the percentage of abnormal cells, the morphology, and additional information on subtle diagnostic clues, all of which help in further characterization of the disease and guide further immunophenotypic and molecular analyses.
- **Flow cytometry**: Flow cytometric output data and plots are analyzed using sophisticated software, which help in visual identification of the expression of various antigens of the cells of interest. The analysis and final disease characterization is performed by specialist hematopathologists, based on the recommendations of the WHO.
- **Molecular techniques**: The raw NGS data are run through sophisticated bioinformatics pipelines specifically designed for different assays. The output data are then analyzed by molecular pathologists to differentiate pathogenic from nonpathogenic mutations. The implications of the detected genetic variants are derived from thorough literature search, and, finally, a wholesome evidence-based report is provided to the treating physician.
- The other disease-specific tests conducted include real-time monitoring of BCR-ABL1 copy numbers in chronic myeloid leukemia (CML) patients and promyelocytic leukemia/retinoic acid receptor alpha (PML-RARA) in acute promyelocytic leukemia patients, donor status in bone marrow transplant recipients, clonality studies, and so on, which are discussed in detail further.

3 Collection, Transport, and Processing of Samples

Proper sample collection, transport, storage, and appropriate processing are important preanalytical components of hematological testing. The samples that can be collected for evaluation of a hematolymphoid neoplasm include:

- Peripheral blood
- Bone marrow
- Fine needle aspirates
- Body fluids (e.g., pleural, peritoneal, cerebrospinal fluid (CSF), saliva, buccal swab)

- Solid tissue samples need to be isolated as single suspension by mechanical (slicing, mincing, and teasing using appropriate devices) or enzymatic methods (trypsinization).
- Bone marrow aspirate slides—in specific circumstances, like unavailability of an adequate sample, DNA can be extracted from stained or unstained bone marrow aspirate slides also.

The type of sample, quality, quantity, and anticoagulant used all play key roles in the reliability and accuracy of any test, which is to be performed. For immunophenotypic analysis and molecular techniques, the conditions recommended are discussed below.

3.1 Flow Cytometry

For peripheral blood and bone marrow aspirates, fine needle aspiration (FNA) samples need to be anticoagulated using ethylenediaminetetraacetic acid (EDTA) or heparin and should be analyzed within 24–48 h. Samples like CSF, which degrade rapidly, need to be analyzed within 1 h of collection. In case of any delay in sample processing, the samples need to be stored in stabilization media, e.g., homemade media containing Roswell Park Memorial Institute (RPMI) and 5% fetal bovine serum (FBS) or commercial media like TransFix (Cytomark, UK) [2].

Once the sample is received in the laboratory, the antigens to be tested on that particular sample are determined by integration of information like clinical history, morphological evaluation of cells, other laboratory findings, and any previous flow cytometry (FC) findings.

3.2 Molecular Techniques

EDTA is the preferred anticoagulant for the collection of whole blood and bone marrow specimens [3]. A total of 5 mL of peripheral blood is usually adequate at the diagnostic time point [if the total white blood cell (WBC) count is not low], but a minimum of 10–20 mL is recommended for follow-up samples [4].

If needed, sample transport should be carried out in compliance with the norms of the International Air Transport Association [3].

Blood scheduled for DNA analysis can be stored at room temperature for up to 24 h or at 2–8 °C for up to 72 h prior to DNA extraction. Blood scheduled for cellular RNA analysis should be collected in a tube containing an RNA-stabilizing additive [3]. It is generally accepted that samples should be processed for RNA extraction as soon as possible. Reliable quantification is not possible from a follow-up sample older than 72 h [4].

Once isolated, DNA is stable at 2–8 °C for at least 1 year. Purified RNA is best stored as a precipitate in ethanol at −70 °C or lower [3].

4 General Techniques

The general techniques employed in a hematopathology laboratory are described.

4.1 Cell Counts, Morphology, and Cytochemistry

A complete blood count including a seven-part differential of the WBCs is obtained by automated analyzers; blast count is further confirmed manually. The blood and bone marrow aspirate slides are prepared and stained using Romanowsky dyes for proper evaluation. The slides are evaluated under a microscope, and a manual 500 cell differential is performed by trained pathologists. Special stains and cytochemistry are used for demonstrating the iron stores, myeloperoxidase (MPO) positivity, and neuron-specific enolase (NSE) positivity. Other special stains like periodic acid–Schiff (PAS) can also be used.

4.2 Red Cell Lysis

Both flow cytometry and molecular techniques use white blood cells (WBCs) as the cells of interest. Therefore, red cells are lyzed before processing for these tests. Red blood cell (RBC) lysis is performed using an ammonium chloride-based lysis buffer and, then, the nucleic acids are extracted.

5 Flow Cytometry

Flow cytometric immunophenotyping (FCI) is an integral part of an investigation of hematological neoplasms and it helps in the diagnosis, classification, prognosis, and monitoring of the treatment response.

5.1 Principle

Flow cytometry (FC) is both a qualitative and quantitative technique that deals with the measurement of cells in suspension, where the cells are made to flow in a single line one after the other (laminar flow) with the help of hydrodynamic focusing (using isotonic sheath fluid). Cells from peripheral blood, bone marrow, serous cavity fluids, cerebrospinal fluid, and solid tissues (obtained by fine needle aspiration cytology or teasing the tissue biopsy) can be analyzed in terms of size, internal complexity, antigens present on the cell membrane surface and/or intracellular components (using fluorescent-labeled antibodies), and DNA and RNA content using multiparameter FC [5]. Cells in the sample analyzed are thus assigned particular lineage and maturity status (progenitors or mature cells) depending on the antigens they express, which can be used to arrive at a diagnosis.

5.2 What Happens Inside a Flow Cytometer?

An individual cell going through the laminar flow strikes the laser beam and scatters laser light in different directions. One part of the light, at a low angle along the axis of the laser beam, is in proportion to the cell size and is known as forward scatter (FSC), whereas another part of the light gets scattered at a right angle, which is in proportion to cell complexity (determined by cell granularity and nuclear characteristics), and is known as side scatter (SSC). Based on these scatter properties, the nature of the cell being analyzed can be accurately determined.

Laser light also excites fluorochrome dyes conjugated with monoclonal antibodies attached to respective antigens on the cell, resulting in the emission of fluorescent light of particular wavelength [6]. This is further separated by a series of optical filters and mirrors and is measured by individual detectors, resulting in the generation of electronic data, which are analyzed by FC software. Depending on the capacity to measure a number of fluorochromes simultaneously, flow cytometers are usually categorized as 6-color, 8-color, 10-color, etc.

5.3 Indications

The Bethesda International Consensus Conference (2006) on the flow cytometric immunophenotypic analysis of hematolymphoid neoplasia has enlisted clinical finding-based indications, as follows [7]:

- Cytopenias
- Leukocytosis
- Detection and subtyping of blasts/atypical cells in peripheral blood and bone marrow and body fluids
- Evaluation of lymphocytosis
- Plasmacytosis
- Lymphadenopathy

5.4 Additional Indications

- Assessment of response to therapy [minimal residual disease (MRD) monitoring]
- Evaluation of prognostic markers
- Enumeration of CD34$^+$ stem cells for stem cell transplantation
- Tumor proliferation index (e.g., Ki67$^+$ tumor cells)
- T-cell clonality assessment (T-cell receptor Vβ repertoire analysis, e.g., in eosinophilia)
- Detecting potential therapeutic targets
- Immune cell profiling assays (T-cell subset enumeration)
- DNA analysis (ploidy, proliferation, i.e., S phase, apoptosis)
- Human leukocyte antigen (HLA) typing
- Cell function studies (e.g., T-cell function)
- RNA detection studies (reticulocytes count)

Suspected patients with hematological malignancies with findings like mature neutrophilia, polyclonal hypergammaglobulinemia, polycythemia, thrombocytosis, and basophilia may not benefit from flow cytometric immunophenotyping (FCI) analysis right now [7].

Common immunophenotypic markers used for diagnosis of hematolymphoid neoplasms are enlisted in Table 1.

5.5 An Overview of Immunophenotypic Analysis of Hematolymphoid Malignancies

5.5.1 Acute Leukemia

Acute leukemia is the most common group of hematolymphoid neoplasms of the pediatric population and constitutes a major group in the adult population as well. The primary step in the diagnosis of acute leukemia is to assign the lineage. Immunophenotyping has come to play an integral role in the enumeration of leukemic populations, assignment of lineage, identification of prognostic subgroups, and subsequent post-therapeutic monitoring [8]. Blasts are abnormal precursors, identified on the basis of their characteristic expression of antigens of immaturity like CD34, CD117, and the absence or decreased levels of maturation antigens. Usually, blast cells show low SSC and dim/absent levels of CD45 expression along with aberrant expression of antigens in the form of lineage infidelity (such as myeloid markers on lymphoblasts or lymphoid markers on myeloblasts). In few cases, leukemic cells express antigens of more than one lineage, making it impossible to assign any one lineage with certainty, which is referred as “ambiguous lineage” [9]. The immunophenotype provides fundamental information to accurately stratify patients and initiate an appropriate therapy.

Table 1 Common antigens used in FCI

Cells	Lineage-associated antigens	Other antigens
Pluripotent stem cells	CD34, CD133	dCD45, CD117, CD123, HLADR
Myeloblasts	MPO, CD117, CD13, CD33, CD15, CD11b	CD34, CD38, dCD45, HLADR
Monoblasts	CD14, CD13, CD11b, CD11c, CD33, CD36, CD64, CD65, CD66, lysozyme, CD86	CD34, CD38, dCD45, HLADR
B lymphoblasts	CD19, cyto/sCD22, cytoCD79a, vCD20	CD10, CD34, dCD45, CD24, CD38, HLADR, nTdT
T lymphoblasts	Cyto/sCD3, CD1, CD2, CD4, CD5, CD7, CD8	vCD10, CD34, dCD45, HLADR, nTdT
Granulocytes	vCD13, vCD11b, bCD15, vCD16, CD33, CD66	vCD10, CD38, mCD45
Monocytes	CD4, CD14, CD13, CD11b, dCD15, bCD33, bCD64, CD68, dCD123, lysozyme	bCD36, CD38, bCD45, HLADR
Basophils	CD13, CD33, bCD123	dCD22, CD38, mCD45,
Eosinophils	CD11a, CD13	CD38, bCD45
Mature B cells	CD19, CD20, CD22, cyto79a, CD79b, surface kappa, surface lambda	CD27, CD38, bCD45, HLADR
Mature T cells	CD2, CD3, CD4, CD5, CD7, CD8, vCD56, vCD57	bCD45
NK cells	CD2, cytoCD3, CD7, vCD8, CD16, CD56, vCD57, CD94, CD158, CD161	bCD45, CD38, HLADR
Plasma cells	CD138, bCD38, CD19, bCD27, CD319, CD229, cyto79a, cyto-kappa, cyto-lambda	dCD45
Erythroid cells	CD235a, CD105, (RBCsCD55 and CD59)	bCD36, bCD71, CD203c
Platelets	CD41, CD42, CD61	–
Dendritic cells	CD123, CD304, CD303	HLADR
Mast cells	bCD117, CD33, CD203c	

b bright, *v* variable, *m* moderate, *d* dim

5.5.2 Acute Lymphoblastic Leukemia (ALL)

Acute lymphoblastic leukemia (ALL) is one of the commonest malignancies in children and accounts for around 20% of acute leukemia cases in adults [10, 11]. Flowcytometric immunophenotyping and DNA index (DI) assessment play a pivotal role in ALL both at diagnosis and during follow-up.

5.5.3 Precursor B-Cell Acute Lymphocytic Leukemia (B-ALL)

B-ALL comprises approximately 80–85% of ALLs [7]. The blasts cells in B-ALL typically express CD19, CD22 (surface and/or intracellular), CD79a (intracellular), CD10 (known as the common ALL antigen; CALLA), CD20 (in some cases), TdT (nuclear), CD34, HLADR, and variably dim to negative CD45 (Fig. 1). CD19 has the highest sensitivity for the detection of B-cell lineage [9]. In a few cases, they also aberrantly express myeloid antigens like CD13 and CD33. Antigen expression by ALL cells represents their degree of differentiation. The recent WHO classification of B-ALL has been based on underlying cytogenetic abnormalities. Recurrent cytogenetic abnormalities and associated immunophenotypes are described in Table 2 [12–15, 22–25].

A recent WHO (2017) [1] update on hematolymphoid neoplasms has also recognized two distinct high-risk entities of B-ALL as provisional categories, including BCR-ABL-like or Philadelphia (Ph) chromosome-like B lymphoblastic leukemia/lymphoma and B lymphoblastic leukemia/lymphoma with intrachromosomal amplification of chromosome 21 (iAMP21). Ph-like ALL is a high-risk subtype of ALL, and shows gene expression profiling similar to that of BCR-ABL-positive B-ALL with various types of chromosomal rearrangements, involving different genes and many partners [26]. Approximately half of the patients with Ph-like ALLs harbor overexpression of the cytokine receptor-like factor 2 (CRLF2) [27]. CRLF2 genomic rearrangements are strictly associated with its surface overexpression and adherence and is easily detected by FC [28]. B-ALL with iAMP21 is defined as a gain of at least three copies of part of chromosome 21 incorporating *RUNX1* and is usually recognized by fluorescence in situ hybridization (FISH) probes [29].

Normal B-cell precursors (hematogones) also express CD10, CD19, CD22, CD34, and variable CD20; however, they show typical and reproducible maturation stages with constant levels of antigen expression, which differ from B-ALL in one or more aspects. Hence, knowledge of normal B-cell precursors helps in identifying residual tumor cells in B-ALL [9]. In addition, hematogones do not show aberrant expression of myeloid antigens like leukemic cells do, making FCI successful in the detection of MRD in B-ALL.

5.5.4 Precursor T-cell Acute Lymphoblastic Leukemia/Lymphoma (T-ALL)

Detection of (cytoplasmic) CD3 expression is a tell-tale sign for T-cell lineage assessment. Other T-cell lineage markers are CD1a, CD5, CD7, and CD2. The antigens indicating the precursor nature of T-lymphoid blasts are TdT, CD99, and CD34. The majority of T-ALL show lack of CD4 and CD8 expression; however, co-expression of CD4 and CD8 can also be seen. A subset of the T-ALL cases expresses variable CD10. T-ALL blasts can also show aberrant myeloid antigen expression, e.g., CD13 and CD33.

According to the European Group for the Immunologic Classification of Leukemias (EGIL), T-ALL can be divided into the following subtypes: (1) pro-T ($cCD3^{+}$, $sCD3^{-}$, $CD1a^{-}$, $CD2^{+}$, $CD5^{-}$, $CD7^{+}$, $CD34^{-}$, $CD4^{-}$, $CD8^{-}$), (2) pre-T/immature ($cCD3^{+}$, $sCD3^{-}$, $CD1a^{-}$, $CD2^{+}$, $CD5^{+}$, $CD7^{+}$, $CD34^{-}$, $CD4^{-}$, $CD8^{-}$), (3), cortical T ($cCD3^{+}$, $sCD3^{+/-}$,

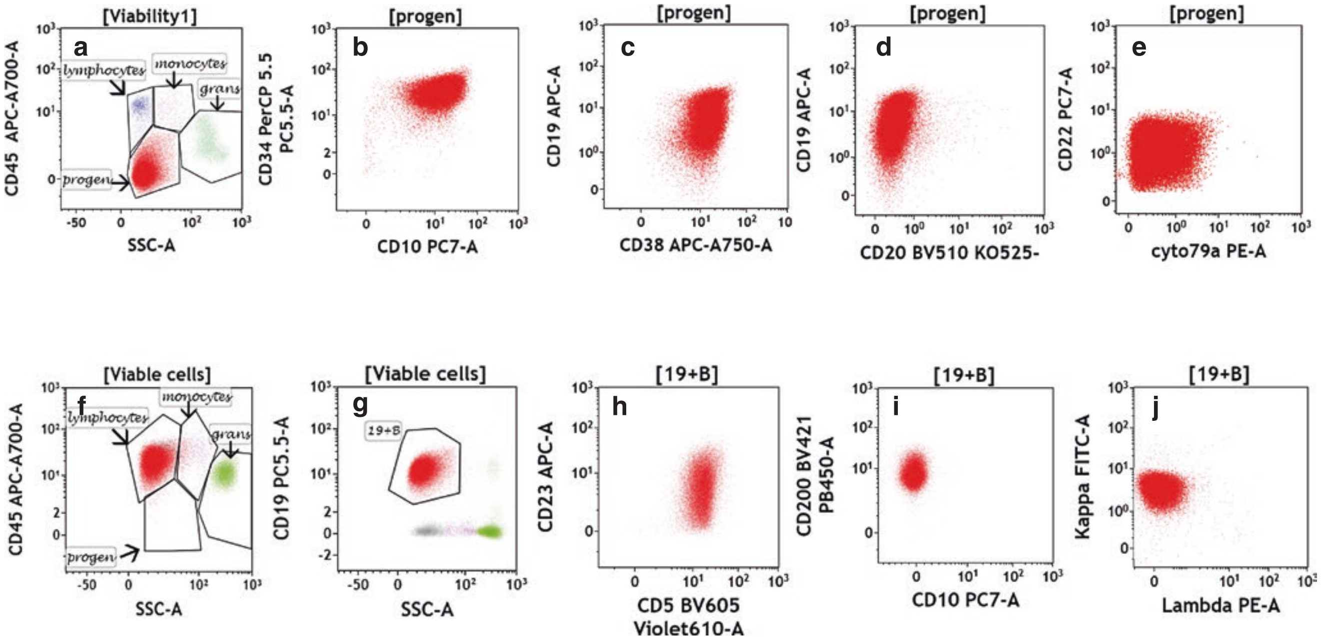

Fig. 1 Plots (**a**–**e**) represent a case of B-cell precursor lymphoblastic leukemia. Based on CD45 expression and SSC, WBCs are divided into lymphocytes, monocytes, granulocytes, and progenitors (**a**). Cells in the progenitor region are blasts and express dim CD45 (**a**), CD34 (immature marker) and CD10 (**b**), CD19 (B lineage-specific) and CD38 (**c**), are negative for the mature B marker CD20 (**d**), and express dim expression of CD79a and CD22 (**e**). Plots (**f**–**j**) represent a case of chronic lymphocytic leukemia. Based on CD45 expression and SSC, WBCs are divided in to lymphocytes, monocytes, granulocytes, and progenitors (**f**). The progenitor gate does not show any cells (**f**). Lymphocytes are gated with the help of CD19 to separate B lineage cells (**g**). These cells express bright CD45, CD5, CD23, and CD200 and are negative for CD10 (**h**, **i**). These cells are clonal and show kappa restriction (**j**)

Table 2 Acute leukemia with recurrent cytogenetics and their associated immunophenotypes

A. B-ALL with recurrent cytogenetics and associated immunophenotypes				
Recurrent cytogenetics	Morphology	Immunophenotype	Prognosis	References
B-ALL with t(4;11) *MLL/AF4* proB phenotype	No unique morphology distinguishing from other ALL types	CD10(N), CD15(D), NG2(P)	Poor	[10, 11]
B-ALL with t(12;21) *TEL/AML1*	No unique morphology distinguishing from other ALL types	CD13(P)	Favorable, few late relapses	[12]
B-ALL with t(9;22) *BCR/ABL*	No unique morphology distinguishing from other ALL types	CD13(V), CD33(V), CD25(P), CD10(B)	Poor	[13]
B-ALL with t(1;19) *TCF3/PBX1*	No unique morphology distinguishing from other ALL types	CD9(B), CD10(D)	Poor, CNS relapse	[14, 15]
B-ALL with hyperdiploidy	No unique morphology distinguishing from other ALL types	CD10(B), CD45(N)	Favorable	[9, 14]
B. AML with recurrent cytogenetics and associated immunophenotypess				
AML with t(8;21) (q22;q22); *RUNX1-RUNX1T1*	Large blasts with abundant basophilic cytoplasm, numerous granules, long thin slender auer rods, perinuclear Hof s. Granulocytic series show dyspoeisis	CD34(B), CD13(B), CD33(N/D), MPO(B), CD19(D), TdT(D), CD56(P/N)	Good KIT mutations and/or CD56 expression indicates adverse prognosis	[16, 17]
AML with inv(16) (p13.1q22) or t(16;16) (p13.1;q22); *CBFB-MYH11*	Myelomonocytic morphology, increased eosinophils of all stages of maturation and basophils	CD34(B), CD117(B), CD14(P), CD11b(P), CD4(P), MPO(P), CD2(P/N)	Good KIT mutations, older age, high white cell count, and *FLT3* mutations indicate adverse prognosis	[9, 18]
Acute promyelocytic leukemia with t(15;17) (q22;q12); *PML-RARA*	Hypergranular abnormal promyelocytes, faggot cells, hypogranular bilobed cells in a microgranular variant	CD34(N), HLA-DR(N), CD15(N/D), MPO(P), CD56(P/N)	Good CD56 expression indicates adverse prognosis	[19]
AML with t(9;11) (p22;q23); *MLLT3-KMT2A(MLL)*	Monoblasts and promonocytes	CD34(N/P), CD13(N), CD14(P/N), CD11b(P), CD4(P), MPO(P), CD19(N/P), NG2(P)	Intermediate MECOM overexpression associated with poor outcome	[9, 20]

B. AML with recurrent cytogenetics and associated immunophenotypess				
AML with t(6;9)(p23;q34); *DEK-NUP214*	Increased basophils; granulocytic and erythroid dysplasia	CD64(P), MPO(P), CD9(P), TdT(P)	Poor High frequency of *FLT3-ITD*	[9, 18, 20]
AML with inv(3)(q21q26.2) or t(3;3)(q21;q26.2); *RPN1-MECOM(EVI1)*	Dysplasia in all three series in bone marrow and peripheral blood neutrophils show Pelger–Heut anomaly	CD34(P), CD117(P), CD13(P), HLA-DR(P), CD7(P)	Poor	[20, 21]
AML (megakaryoblastic) with t(1;22)(p13;q13); *RBM15-MKL1*	Medium-to-large sized blasts, basophilic cytoplasm, blebs, bilobed blasts, micromegakaryocytes	CD61(P), CD41(P), MPO(N)	Poor	[9, 20, 21]
AML with *BCR-ABL* (provisional entity) CML and MPAL should be ruled out before diagnosing this entity	No characteristic morphology, lower peripheral blood basophilia compared to CML	CD34(P), CD13(P), CD33(P), CD19(P/N), CD7(P/N), Tdt(P), CD25(p)	Poor	[8, 21]
AML with mutated *NPM1*	Monoblasts, nuclear cupping in the blasts	CD34(N), CD14(P), CD64 (P), CD36(P), CD123(P)	Good presence of *FLT3-ITD* mutations indicate poor prognosis	[8]
AML with biallelic mutations of *CEBPA*	No characteristic morphology	CD34(P), CD13(P), CD33(P), CD15(P), CD7(P)	Good	[8]

B bright, *D* dim, *P* positive, *N* negative, *V* variable

CD1a$^+$, CD2$^+$, CD5$^+$, CD7$^+$, CD34$^-$, CD4$^+$, CD8$^+$), and mature/medullary-T (cCD3$^+$, sCD3$^+$, CD1a$^-$, CD2$^+$, CD5$^+$, CD7$^+$, CD34$^-$, CD4$^{+/-}$, CD8$^{+/-}$) [30]. Few studies have claimed a correlation between the stages of T-cell differentiation in T-ALL and survival [31]. However, with modern chemotherapy and MRD-based risk stratification, developmental stages lose their prognostic significance. A novel unique subgroup has been recently described as early T-cell precursor-ALL (ETP-ALL), which shows characteristic immunophenotypic features, like lack of CD1a and CD8 expression, weak CD5 expression, and expression of at least one myeloid and/or stem cell marker [32]. Patients with this form of leukemia had a high risk of remission failure or hematological relapse [32].

5.5.5 Acute Myeloid Leukemia (AML)

FCI plays a major role in the establishment of the myeloid lineage and illustrates the nature of differentiation such as granulocytic, monocytic, erythroid, or megakaryocytic. It also objectively provides information on associated dysplasia and helps in the diagnosis of AML with multi-lineage dysplasia [32]. Most importantly, a detailed immunophenotypic expression aids in the detection of MRD, which has a significant role in both prognosis and therapy.

Blasts in AML typically express dim CD45, CD34, and HLADR along with myeloid antigens like CD13, CD33, CD117, and cytoplasmic MPO and, less frequently, CD15, CD11b, and CD66 [9]. The expression of at least two monocytic antigens such as CD14, CD4, CD11b, CD11c, CD36, CD64, and CD68 and lysozymes is required to define the monocytic differentiation of blasts [18, 33]. Expression of CD235a (glycophorin A), CD71, and CD36 and lack of CD64 indicates erythroid nature. Similarly, CD41, CD61, CD42 (less frequently), and lack of CD34 and HLADR indicate the megakaryocytic nature (acute megakaryoblastic leukemia) [16, 18, 34].

The recent WHO classification of AML has mainly categorized AML on the basis of associated cytogenetics into a distinct group called AML with recurrent cytogenetics. The morphology, immunophenotypic expression, and prognosis associated with an individual subgroup of this category are all shown in Table 2 [13, 17, 19–21, 35–38].

5.5.6 Recently Described Immunophenotypic Subgroup in AML

A unique diagnostic immunophenotype (the RAM phenotype) in otherwise standard risk pediatric patients was described, which shows the absences of HLADR, CD38, dim-to-negative CD45, and bright CD56 with a high induction failure rate and extremely poor outcome [39].

5.5.7 Blastic Plasmacytoid Dendritic Cell Neoplasms (BPDCNs)

A BPDCN is an aggressive blastic neoplasm originating from plasmacytoid dendritic cells (PDCs) and is a separate entity in the current WHO classification [40, 41]. The blasts co-express CD4, CD56, and CD123 in association with other markers like CD2, CD5, CD303, CD7, CD13, CD33, CD68, etc. They are specifically negative for CD11c, CD14, CD34, CD117, and cytoplasmic MPO. One-third of cases show TdT positivity [40, 41].

5.5.8 Acute Leukemia of Ambiguous Lineage

According to the WHO-provided guidelines [10], lineage can be defined as follows:

- *Myeloid lineage*: Expression of MPO

In monocytic differentiation, at least two of CD11c, CD14, and CD64 and lysozyme antigens

- *B Lineage*: Bright CD19 along with bright expression of one or more of CD10 or cytoplasmic CD22 or CD79a

Dim CD19 with a bright expression of two or more of CD10 or cytoplasmic CD22 or CD79a

- *T Lineage:* Surface or cytoplasmic expression of CD3

Any leukemia that cannot be categorized into one of the above three lineages is categorized as belonging to the ambiguous lineage, which includes mixed phenotype acute leukemia (MPAL) and acute undifferentiated leukemia.

5.5.9 Flow Cytometric Analysis of Mature Lymphoid Neoplasms

The WHO classifies mature lymphoid neoplasms by integrating their morphology, immunophenotypes, genetic abnormalities, and clinical features. FCI is an integral part of an investigation of mature lymphoid neoplasms in the diagnosis, classification, prognosis (in few subgroups), and monitoring of treatment response. In non-Hodgkin's lymphoma diagnosis, FC is a more sensitive, specific, and rapid tool when compared to immunohistochemistry. Of note, flow cytometry has high efficacy when evaluating lymphoid neoplasms for antibody-based therapy (such as rituximab, alemtuzumab), as it specifically identifies the surface expression of the targeted antigen.

Mature B-Cell Neoplasms

Mature B-cell neoplasms are a clonal expansion of B cells (expressing either kappa or lambda light chain) and are usually associated with immunoglobulin (Ig) gene rearrangement. In addition to lineage assignment, FCI plays a pivotal role in B-cell non-Hodgkin's lymphoma by determining clonality, i.e., Ig light chain restriction, identifying the size of the cells (large or small), and evaluating aberrant antigen expression. In a normal or reactive B-cell population, the ratio of surface kappa light chain-expressing B cells to surface lambda light chain-expressing B cells is 4:1–1:1 and a deviation from this range alerts the underlying monoclonal B-cell proliferation [42]. Of note, the kappa–lambda ratio may be unable to detect small monoclonal populations whenever admixed with reactive polyclonal B cells and, in such cases, the light chain ratio needs to be evaluated after separation of selective B cells with atypical antigen expression [43]. The absence of surface immunoglobulin (sIg) light chains in mature B-cell proliferation also indicates a mature B-cell neoplasm [43, 44].

Classification

Mature B-cell neoplasms are assigned a lineage based on their expression of one of the lineage-specific markers like CD19 (most specific), CD22, CD79a, CD79b, and CD20. Traditionally, some researchers classified mature B-cell neoplasms based on their expression pattern of CD5 and CD10 into four arbitrary subgroups such as [25]:

1. CD5$^+$, CD10$^-$ [chronic lymphocytic leukemia (CLL), mantle cell lymphoma (MCL), B-cell prolymphocytic leukemia (B-PLL)]
2. CD5$^-$, CD10$^+$ [follicular lymphoma (FL), diffuse large B-cell lymphoma (DLBCL), Burkitt's lymphoma (BL)]
3. CD5$^-$, CD10$^-$ [marginal zone lymphoma (MZL), DLBCL, lymphoplasmacytic lymphoma (LPL), hairy cell leukemia (HCL)]
4. CD5$^+$, CD10$^+$ (FL, DLBCL, BL)

Once the arbitrary grouping is done, more specific antigens are studied to distinguish each entity from the other in particular subgroups. The majority of cases in CD5$^+$, CD10$^-$ lymphoma subgroups are constituted by CLL and MCL, which can be distinguished by markers like variable CD23, moderate CD200, dim CD20, and dim surface Ig in CLL (see Fig. 1) vs. negative CD23, negative CD200, moderate-to-bright CD20, and moderate surface Ig in MCL [43, 45]. Further confirmation of MCL can be performed by cyclin-D1 studies [46]. Atypical CLL (aCLL), a distinct clinical and immunophenotypic entity, differs from classical CLL by expressing bright CD20 and bright surface Ig [47]. B-PLL is a morphological diagnosis with peripheral blood showing >55–90% prolymphocytes and immunophenotypically expressing bright CD19, bright CD20, bright IgM/IgD, less frequently CD5 and CD23, and dim CD200 [47]. A subset of DLBCL is CD5$^+$ and can be differentiated from small cell CD5$^+$ lymphomas by their morphological size and an associated high FSC [25]. CD5$^+$ MZL lymphomas constitute a small subset, and it is difficult to distinguish from other CD5$^+$ lymphomas [25].

FL is characterized by the expression of dim CD19, CD10, and intracellular bright homogeneous BCL2 expression [48, 49]. DLBCL is a heterogeneous category, with 20–40% of them being CD10$^+$, and can be sometimes distinguished from grade 3 follicular lymphomas by the size of the cells and also the presence of t(14,18) [50, 51]. BL is a high-grade lymphoma with distinctive morphological features like large cells, with bluish cytoplasm, cytoplasmic vacuoles, and characteristic immunophenotypic features like a moderate expression of CD19, CD20, CD38, CD10, CD81, and variable CD86 and the absence of BCL2 and positive expression of BCL6 [51]. Sometimes it is difficult to distinguish from DLBCL by morphology and immunophenotyping, which can be solved by a demonstration of t(8;14).

Hairy cell leukemia (HCL) is another example where FCI plays the foremost role in diagnosis as well as in residual disease monitoring and is characterized by cells showing high FSC and SSC and bright expression of B-cell antigens like CD19, CD20, and CD22 in combination with co-expression of CD11c CD25, CD103, CD123, and CD305 [52, 53]. The HCL variant shows a similar phenotype, except for the characteristic absence of CD25 and CD123 [9]. It is difficult to distinguish LPL from MZL, as the majority of the cases in both entities are CD5C and D10, along with moderate expression of CD19 and CD20. Few features that can help in diagnosing LPL are serum monoclonal M-band in case of LPL, bright immunophenotypic expression of IgM, and demonstration of clonal plasma cells [11].

Mature T- and Natural Killer (NK)-Cell Neoplasms

Mature T- and NK-cell neoplasms are relatively rare when compared with B-lineage non Hodgkin lymphoma (NHL). These neoplasms aberrantly lack one of the following T-cell antigens: CD2, CD3, CD5, and CD7. In most of the cases, there is CD4- or CD8-restricted population ($CD4^+$ is more common). Also demonstrated are $CD8^+$ T-cell lymphomas, $CD4^+$ and $CD8^+$ lymphomas, and double-negative lymphomas [43]. Apart from the aberrant loss of antigens and CD4/CD8 restriction, it is important to establish clonality using T-cell receptor (TCR) Vβ repertoire FC analysis [54]. Mycosis fungoides (MFs), Sezary syndrome (SS), T-cell prolymphocytic leukemia (T-PLL), anaplastic large cell lymphoma (ALCL), adult T-cell leukemia/lymphoma (ATLL), and angioimmunoblastic T-cell lymphoma (AITL) constitute the majority of the $CD4^+$ T-cell neoplasms [43]. T-cell neoplasms can be further classified into these subtypes by clues like frequent loss of CD7, the absence of CD26 and skin lesions in MFs [9], $CD30^+$, ALK^+ large cells, and frequent loss of CD5 in ALCL [43]. Frequent loss of CD7, high levels of CD25, and serological evidence of HTVL favor ATLL [43]. CD10, PD-1, BCL2 and other follicular markers help in the diagnosis of AITL [25]. T-PLL is characterized by a high peripheral blood WBC count (>1 lakh) and T-cell leukemia/lymphoma 1 (TCL1) expression [9, 10].

5.5.10 Flow Cytometric Analysis in Plasma Cell Neoplasms (PCNs)

FCI is widely used in the diagnosis of PCNs, including a precursor condition, monoclonal gammopathies of undetermined significance (MGUS). Plasma cells (PCs) are gated by taking into account the expression of CD38 (bright) and CD138 (bright). Together with CD38 and CD138, normal PCs express dim CD19, bright CD27, dim CD45, and cytoplasmic Ig light chains (kappa and lambda) and are negative for other lymphoid and myeloid antigens [55]. PCs typically show high FSC and relatively high SSC. Neoplastic PCs characteristically show the following immunophenotypic features [55]:

- Loss of normal antigens, e.g., CD19 and CD45
- Decreased expression of antigens, e.g., CD38 and CD27
- Aberrant expression of antigens, e.g., CD56, CD20, CD28, and CD117
- Cytoplasmic Ig light chain restriction, e.g., either kappa or lambda

Novel applications of FCM in plasma cell neoplasms include prognostication, identification of potential therapeutic target antigens, and detection of minimal residual disease (MRD) for monitoring of treatment response [9].

5.5.11 Flow Cytometric Analysis in Myelodysplastic Syndromes (MDS)

Myelodysplastic syndromes (MDS) are a heterogeneous group of clonal hematopoietic stem cell disorders characterized by dysplastic features of erythroid and/or myeloid and/or megakaryocytic lineages with a varying percentage of blast cells. FCI plays a crucial role in MDS diagnosis by detecting maturation asynchrony and aberrant antigen expression on multiple bone marrow lineages (in comparison to normal cells of that particular lineage) [56]. It also analyzes aberrancies on myeloid and lymphoid progenitors and can be utilized to quantify the progenitor percentages. Normal hematopoietic cells show reproducible patterns of antigen expression and synchronous maturational patterns compared to normal, dyspoietic cells in MDS, which show the following:

- Increased or decreased intensity and/or loss of normal antigens
- Asynchronous maturation
- Aberrant expression of antigens (lineage infidelity)

The antigens commonly used for illustration of asynchronous maturation patterns in granulocytes are CD11b, CD13, CD15, CD16, CD33, CD34, CD45, CD117, and HLADR; in monocytes, they are CD13, CD14, CD15, CD33, CD36, CD45, CD64, and HLADR; in erythroid cells, they are CD36, CD71, CD105, and CD235a; and for aberrant antigen detection, they are CD2, CD7, and CD56. Based on the number and types of these immunophenotypic abnormalities in blasts, granulocytes, and monocytes, several scoring systems have been published (flow cytometric scoring system (FCSS) like WELLS score, Ogata score, Red score) [57–59]. The European LeukemiaNet Working Group showed a correlation between higher numbers of immunophenotypic aberrancies and increased risk of progression in MDS [60].

5.5.12 Minimal Residual Disease (MRD) Monitoring by FC

Minimal residual disease refers to an extremely low-level neoplastic cell population that can be detected by sensitive laboratory techniques like flow cytometry (immunological MRD) or polymerase chain reaction (PCR) (molecular MRD) in cases with morphological remission at different time points during treatment like day 15 of induction, post-induction, post-consolidation, or at the end of maintenance. FC analysis of MRD is based on two main principles:

- Deviation from normal maturation (neoplastic cells do not follow normal maturation, which is exhibited by their corresponding normal regenerating precursors)
- Identification of leukemia-associated immunophenotypes (LAIPs), which are not expressed by normal bone marrow (BM) or peripheral blood cells, e.g., lymphoid blasts expressing myeloid antigens, or vice versa, as mentioned under ALL and AML.

It is a strong prognostic indicator, depending on which treatment protocols are decided in cases of ALL [61]. In AML, MRD by FCI has a pivotal role in the response and risk assessment in AML and a means of identifying risk groups in patients with otherwise no prognostic markers (cytogenetically normal AML and the absence of molecular subgroups) [62]. FCI can successfully detect and quantify MRD levels up to 1 leukemic cell in 10^4 normal cells and is widely applied in monitoring not only acute leukemia but also mature lymphoid neoplasms like multiple myeloma (MM), CLL, HCL, etc. [9], and its role in acute leukemia is well-established. Recent studies have proven that high-sensitivity FC-MRD (by simply acquiring a higher number of events, more than four million cells) will improve the sensitivity (1 tumor cell in 10^5–10^6) of FC-based MRD comparable to molecular MRD [63].

5.6 The Role of FCI in the Prognosis of Hematolymphoid Neoplasms

FC also plays an important role in identifying the prognostic markers in many hematolymphoid neoplasms, which are described in Table 3 [64].

Table 3 Immunophenotypic markers useful in prognosis of hematolymphoid neoplasms

Disease entity	Immunophenotypic markers	References
CLL	CD38, ZAP 70, and CD49d	[62]
B-ALL	Absence of CD10, CD15 POS, NG2 predicts *MLL* rearrangement	[10]
B-ALL	CRLF2 expression predicting Ph-like ALL	[24, 25]
T-ALL	ETP-ALL phenotype with negative CD5, CD8, and CD1a	
AML	RAM phenotype with the absence of HLADR, CD38, dim-to-negative CD45, and bright CD56	[36]
AML	CD56 expression in general	[21]

6 Molecular Hemato-Oncology

Molecular diagnostic techniques are now quintessential, as in the current World Health Organization (WHO) classification of hematopoietic and lymphoid neoplasms [1]; several entities have been essentially defined by their molecular abnormalities.

This section discusses the most used molecular diagnostic assays deployed in a state-of-the-art molecular hemato-oncology laboratory. Because molecular testing is most commonly performed in the context of neoplastic disorders, this section follows the outline of the entities incorporated into the WHO classification.

6.1 An Overview of Molecular Diagnostic Techniques

The basic workflow in a molecular laboratory is depicted in Fig. 2. Once a sample is received, the type of nucleic acid to be extracted (DNA or RNA) depends on the test requested. For most of the point mutation analysis, DNA-based panels are used, whereas for detection of fusions, RNA-based assays are employed. Following nucleic acid extraction, RNA is reverse-transcribed to complementary DNA (cDNA) for further processes. The segment of interest is then exponentially amplified (PCR) using gene-specific primers. PCR entails three steps:

1. **Denaturation** of the nucleic acid—(90–95 °C)
2. **Annealing**—primer binding—(40–70 °C)
3. **Extension**—(70–75 °C)

Once the product is amplified, the amplicons can be analyzed using any of the myriad techniques available

- **Gel electrophoresis**: This is the traditional method of post-PCR analysis. This process involves labeling of the DNA fragments with ethidium bromide (intercalating DNA-binding dye). This technique has been largely replaced by capillary electrophoresis and restriction fragment length polymorphism (RFLP).
- **RFLP**: This involves fragmentation of the amplicons by restriction endonuclease enzymes, which act upon specific nucleotide sequences, leading to the detection of a specific pattern on gel.
- **Sanger sequencing**: DNA sequencing determines the precise order of the four bases (A, T, G, and C) in a given

template. Sanger sequencing is the conventional method, which involves DNA synthesis coupled with chain termination. It uses fluorescent-labeled chain terminators, which are modified dideoxynucleotide triphosphates (ddNTPs), in which the 3′-OH group, required for DNA extension, is missing. Thus, labeled fragments of different sizes are obtained, which are then subjected to capillary electrophoresis. The resulting graph is called a chromatogram, which is then aligned with the reference gene to determine the sequence and the variant.

- **Next-generation sequencing (NGS)**: Next-generation sequencing is the more sophisticated technology, which has been developed on the premise of sequencing by synthesis. It involves simultaneous analysis of millions of fragments of DNA, all incorporated within a single test [65, 66]. The library preparation involves complex sequential steps, which finally hybridizes to a two-dimensional flow cell. The bridge-amplification cycle then sets in, culminating in a localized cluster of approximately 2000 similar libraries in a 1-μm diameter. Using sophisticated bioinformatics pipelines, the massive raw data are analyzed to detect the variants. Many platforms are available—Illumina, Roche, and Ion torrent. Similarly, fusions can be looked for by designing primers against the expected fusions or using an anchored multiplex PCR approach, which helps detect novel fusions when one of the partners is known. This technique can also be used to monitor minimal residual disease in acute leukemia during and after treatment.
- **Short tandem repeat (STR)**: STR analysis is the most frequent method for monitoring of donor engraftment after transplant. STRs are polymorphic 2–6 nucleotide tandem repeats that are distributed throughout the genome. Differentiation between individual genomes can be detected owing to the highly polymorphic nature of these STRs. This enables earlier detection of disease relapse, level of donor engraftment, and graft-versus-host disease/graft-versus-tumor effect, thus facilitating therapeutic decisions and interventions. A baseline analysis of both the patient and the donor is necessary to identify informative markers, which can be later used for monitoring of the donor engraftment status [67].
- **Real-time quantitative PCR (RQPCR)**: Real-time PCR monitors the PCR amplification process and detects the amplicons in real time, i.e., when they are produced. In RQPCR, amplification and detection are coupled into a

single step, which helps the detection of amplicons as they are produced. The most common application of this technique in the molecular hematopathology setting is the detection of minimal residual disease (MRD) in patients of chronic myeloid leukemia. The details of the same are discussed under the heading "Chronic Myeloid Leukemia (CML)."

The various assays and their use in the diagnosis of hematolymphoid neoplasms are summarized in Table 4.

6.2 Molecular Diagnosis of Hematolymphoid Neoplasms

6.2.1 Myeloproliferative Neoplasms

Chronic Myeloid Leukemia (CML)

As per the current definition by the WHO, all cases of CML harbor t(9; 22) (q34; q21) and, in approximately 5% cases, other complex or variant translocations involving the *BCR* and *ABL1* genes. The breakpoints in the *BCR* gene on chromosome 22 are heterogeneous and, in most cases, involve exons 13 or 14 of the *BCR* gene, producing a 210-kDa fusion protein (M-bcr). However, in a subset of cases and in few cases of precursor B-cell acute lymphoblastic leukemia, a 190-kDa fusion protein is produced due to breakpoint at exon 1 (u-bcr) [1]. At the diagnostic time point, the identification of the transcript is imperative, to guide future MRD monitoring in these patients. Several techniques are employed for the detection of the fusion:

- **Classical cytogenetics**: Fluorescence in situ hybridization (FISH) is the age-old method that is used to detect the *BCR-ABL1* translocation.
- **Multiplex PCR**: This is the method of choice for transcript identification nowadays and has the advantage of detecting other rare variant transcripts using specific primers. After the initial PCR, the products are electrophoresed on a gel and the specific sizes of the bands guide transcript identification. Rare transcripts detected can be subsequently sequenced for validation [68].
- **RQPCR**: This can also detect the transcripts and quantify the copy number. Baseline copy number detection before initiation of therapy is imperative for future monitoring. Following complete cytogenetic response, RQPCR is

Table 4 Commonly tested molecular abnormalities and methodologies in hemato-oncology

Disorder	Abnormality	Commonly used method for testing
Chronic myeloid leukemia, *BCR-ABL1*-positive	*BCR–ABL1* fusion	RT-PCR
	Molecular monitoring while treatment	RQPCR
	ABL1 kinase domain mutation testing	Sanger sequencing/NGS
Philadelphia-negative myeloproliferative neoplasms	*JAK2 V617F*	RQPCR/ASO-PCR
	CALR	Fragment length analysis
	JAK2 exon 12	Fragment length analysis Sanger sequencing
	MPL W515K/L	Fragment length analysis
Chronic lymphocytic leukemia	*IgH*V mutation analysis	Sanger sequencing
	TP53 mutation analysis	Sanger sequencing/NGS
Acute myeloid leukemia	*FLT3/ITD*	Fragment length analysis
	FLT3/TKD	RFLP
	NPM1	Fragment length analysis/NGS
	CEBPA	Fragment length analysis Sanger sequencing
	c-KIT	Sanger sequencing/ASO-PCR
	Other mutations (*DNMT3A*, *TET2*, *IDH1*, *IDH2*, etc.)	NGS
	Recurrent genetic abnormalities (e.g., *PML-RARA*, *RUNX1-RUNX1T1*, *CBFB-MYH11*, etc.)	RT-PCR
	Monitoring of *PML-RARA*	RQPCR
MDS	*SF3B1*	Sanger sequencing/NGS
	Other mutations (*DNMT3A*, *TET2*, *IDH1*, *IDH2*, etc.)	NGS
Acute lymphoblastic leukemia (ALL)	Recurrent genetic abnormalities	RT-PCR
	BCR-ABL1-like ALL	NGS or MLPA + RQPCR + Sanger sequencing
Hairy cell leukemia	*BRAF V600E*	ASO-PCR
Lymphoplasmacytic lymphoma	*MYD88 L265P*	ASO-PCR
Chimerism testing	STRs	Multiplex PCR + fragment length analysis
Clonality	Ig and TCR gene rearrangement	Multiplex PCR + fragment length analysis

PCR polymerase chain reaction, *RT* reverse transcriptase, *RQ* real-time quantitative, *ASO* allele-specific oligonucleotide, *NGS* next-generation sequencing, *RFLP* restriction fragment length polymorphism, *Ig* immunoglobin, *TCR* T-cell receptor

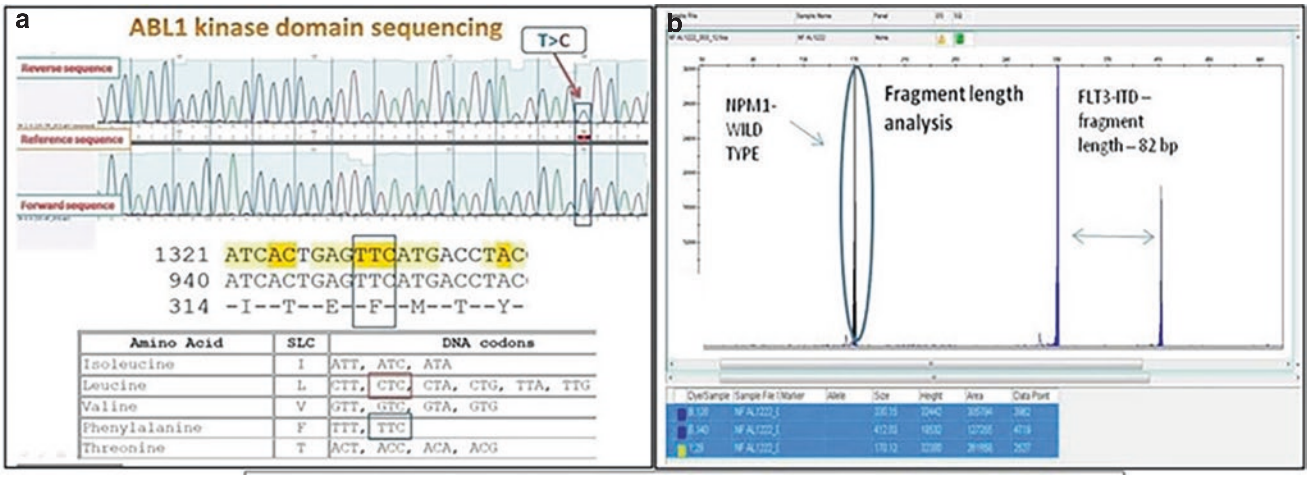

Fig. 3 (**a**) Determination of mutation by bidirectional Sanger sequencing. Here, the bases in TTC (which encode for phenylanaline) is replaced by CTC (encoding for leucine) and hence amino acid phenylalanine (F) is changed to leucine (L) at 317 positions. (**b**) Fragment length analysis to depict *NPM1* and *FLT3-ITD* mutation. Here, *NPM1* (black peak-encircled) is wild-type. There is no mutation in exon 12. *FLT3* (blue peak) shows an internal tandem duplication with a fragment length of 82 bp. The allelic ratio can be calculated by dividing the area of the mutant peak by the area of the wild-type peak

advocated and a major molecular response is defined as a 3-log reduction in the number of *BCR-ABL1* transcripts from the pretreatment baseline [4, 69, 70]. Likewise, although the transient positivity or persistent low-level copy numbers are not predictive of impending relapse, a 1-log change in the level is generally considered significant. Therefore, a rising quantitative PCR result offers the possibility of an early intervention.

- **Kinase domain mutation status**: Imatinib, which is the drug of choice for these patients, acts at the kinase domain in the *ABL1* gene. During the course of therapy, acquired point mutations in this kinase domain may lead to imatinib resistance and hence treatment failure. These mutations are diverse, however the T315I mutation is notable amongst them as it imparts resistance to the second generation tyrosine kinase inhibitors [68, 71]. These mutations can be detected by direct sequencing of the fusion gene, traditionally by Sanger's method, or nowadays using NGS. Other methods that can be employed are allele-specific PCR, pyrosequencing, etc. Figure 3a shows the interpretation of a kinase domain mutation using Sanger sequencing.

Philadelphia-Negative Myeloproliferative Neoplasms

Unlike CML, these are not described by a single recurring molecular abnormality. They include primary myelofibrosis (PMF), essential thrombocythemia (ET), and polycythemia vera (PV). The *JAK2 V617F* mutation is identified in >95% cases of PV and 50–60% of PMF and ET, *JAK2* exon 12 mutations in 3% cases of PV, *CALR* (calreticulin) mutations in 30% of PMF and ET, and *MPL* mutations are seen in 8% of PMF and 3% of ET [1]. The most common *CALR* mutation notated are 5-bp insertion and a 52-base pair deletion. Likewise, the common mutations encountered in the *MPL* gene are *W515L* and *W515K*.

The *JAK2 V617F* mutation can be detected using allele-specific oligonucleotide-PCR (ASO-PCR) [72], or RQPCR can be employed to detect low-level mutations, which may be missed by other methods, including NGS. *MPL* and *JAK2* exon 12 mutations can be detected using ASO-PCR, whereas *CALR* mutations can be detected by PCR followed by fragment length analysis [73, 74].

Myelodysplastic/Myeloproliferative Neoplasms (MDS/MPNs)

Recently, whole-genome sequencing has helped identify recurrent mutations in MDS/MPNs, and these have now been incorporated in the diagnostic criteria, for example, *TET2*, *SRSF2*, *ASXL1*, and *SETBP1* mutations in chronic myelomonocytic leukemia, *SETBP1* and *ETNK1* mutations in atypical CML, *PTPN11*, *KRAS*, *NRAS*, *NF1*, and *CBL* mutations in juvenile myelomonocytic leukemia, and *JAK2 V617F*, *CALR*, *MPL*, and *SF3B1* mutations in MDS/MPNs with ringed sideroblasts and thrombocytosis [1].

6.2.2 Myelodysplastic Syndromes

The *SF3B1* mutation is the sole genetic abnormality that is a part of the diagnostic criteria for myelodysplastic syndrome (MDS) with ring sideroblasts. Patients with *TET2* and *DNMT3A* mutations respond well to hypomethylating agents and those with MDS with 5q deletion having the *TP53* mutation respond less well to lenalidomide [1, 75].

Table 5 Myeloid neoplasms with germline predisposition

Myeloid neoplasms with germline predisposition (MNGP)	MNGP without a preexisting disorder or organ dysfunction • AML with germline *CEBPA* mutation • MN with germline *DDX41* mutation MNGP and preexisting platelet disorders • MN with germline *RUNX1* mutation • MN with germline *ANKRD26* mutation • MN with germline *ETV6* mutation MNGP and other organ dysfunctions • MN with germline *GATA2* mutation • MN associated with BM failure syndrome • MN associated with telomere biology disorders • JMML associated with neurofibromatosis, Noonan syndrome, or Noonan syndrome-like disorders • MN associated with Down syndrome

AML acute myeloid leukemia, *MN* myeloid neoplasm, *BM* bone marrow, *JMML* juvenile myelomonocytic leukemia

6.2.3 Myeloid Neoplasms with Eosinophilia and Gene Rearrangements

This category in the WHO includes four distinct entities defined by specific gene rearrangements. These are *PDGFRA*, *PDGFRB*, *FGFR1*, and one with a *PCM1–JAK2* fusion. These can be detected using reverse-transcription-PCR (RT-PCR) or FISH [1].

6.2.4 Myeloid Neoplasms with Germline Predisposition

These are AML or MDS patients with a germline mutation and exhibit distinctive clinical and genetic abnormalities. Table 5 depicts the various entities included under this category. It is important to consider these entities in the setting of high mutant allele burden in a patient with defined clinical features. Germline testing is recommended using DNA from skin fibroblasts [1, 76].

6.2.5 Acute Myeloid Leukemia

According to WHO, seven distinct clinicopathological entities are defined by the presence of specific recurring molecular abnormalities: *RUNX1-RUNX1T1*, *CBFB-MYH11*, *PML-RARA*, *MLL* rearrangement, *DEK-NUP214*, *BCR-ABL1*, and *RBM15-MKL1*. These can be detected by RNA sequencing. Other molecular abnormalities described in AML, which have therapeutic and prognostic implications, include *NPM1*, *FLT3* (*TKD* and *ITD* mutations), *CEBPA*, *c-KIT*, *RUNX1*, and, commonly, *IDH1* and *IDH2*. Next-generation sequencing assays utilizing single-molecule molecular inversion probes are used for the detection of these mutations. *FLT3-ITD* and *NPM1* can additionally be detected using fragment length analysis, as depicted in Fig. 3b *PML-RARA* can be monitored using RQPCR [77, 78].

6.2.6 Clonality Assays in Lymphoproliferative Disorders

Tests for monoclonal rearrangements of the immunoglobulin (Ig) and the T-cell receptor (TCR) loci are commonly performed assays [1]. The results of these assays should be cautiously interpreted in the context of the clinical and morphological findings, excluding the potential false positives and false negatives. These can be detected using PCR followed by capillary electrophoresis.

6.2.7 Precursor B-Cell Acute Lymphoblastic Leukemia/Lymphoma (BCP-ALL)

The RT-PCR approach can be employed to detect few of the recurrent genetic abnormalities, which are found commonly in BCP-ALL. Additionally, for the WHO-defined entities, RNA-based NGS assays, as described earlier in AML, can also be used—*BCR-ABL1*, *TEL-RUNX1*, *MLL* rearrangement, and *GATA2-MECOM*. A new entity incorporated in the recent WHO edition is Philadelphia-like ALL, which can harbor rare fusions that can be detected by the same NGS approach [1, 79].

6.2.8 Precursor T-Cell Acute Lymphoblastic Leukemia/Lymphoma (T-ALL)

Recurrent cytogenetic abnormalities have been described in T-ALL cases; however, a risk-stratified treatment strategy based on molecular abnormalities has not yet been devised; hence, molecular studies for the identification of these abnormalities are rarely performed in routine practice.

6.2.9 B-Cell Lymphoproliferative Disorders

Chronic Lymphocytic Leukemia

Studies have shown that the mutational status of the *IGH* locus carries prognostic significance in CLL. During normal B-cell maturation and activation, the *IGH* locus undergoes somatic hypermutation in the germinal center. By sequencing the portions of the clonally rearranged *IGH*, the mutational status of the neoplastic cells may be determined. The mutated genotype has been associated with a favorable outcome compared to the unmutated genotype [80].

Because patients carrying *TP53* abnormalities are resistant to chemoimmunotherapy, *TP53* mutation analysis should always be performed before initiation of treatment [81].

Hairy Cell Leukemia

Hairy cell leukemia harbors the characteristic *BRAF V600E* mutation, for which targeted therapy (vemurafenib) is available. This can be detected using allele-specific PCR or direct sequencing by any of the methods [82].

Lymphoplasmacytic Lymphoma

MYD88 L265P is a recurring mutation in patients with Waldenström macroglobulinemia that can be helpful in differentiating it from non-IgM LPL and B-cell non-Hodgkin's lymphoma that have similar features [83]. Extremely sensitive and specific ASO-PCR assays have potential benefit in diagnosis and in the assessment of response [84].

6.2.10 T-Cell Lymphoproliferative Disorders

In most cases, the diagnosis of these is rendered on the basis of morphological and phenotypic findings. Clonality studies are useful to confirm the presence of the monoclonal T-cell population. Approximately 60–80% cases of anaplastic large cell lymphoma harbor a translocation involving the *ALK* gene at 2p23. These are best detected using break-apart probes by FISH. However, routinely, immunohistochemistry is used to demonstrate this [1].

6.2.11 Plasma Cell Neoplasms

Cytogenetic abnormalities are present in almost all cases of myeloma, and a subset of these has prognostic implications. The most frequent translocations involve the *IGH* locus [1]. Seven recurrent oncogenes are involved in this translocation: *CCND1*, *MAF*, *FGFR3/MMSET*, *MAFB*, *MAFA*, *CCND2*, and *CCND3*. Mutations in *TP53* and genes in the nuclear factor kappa B (NF-kβ) pathway are associated with tumor progression. These can be detected using direct sequencing of bone marrow samples. Some tumor subclones have RAS pathway mutations, which are important as a specific therapeutic regimen may target one or more specific subclones but have little or no effect on other subclones [1].

Take-Home Points

- Molecular diagnostics is an integral component in the diagnosis of a hematolymphoid malignancy.
- WHO-defined entities necessitate the demonstration of specific molecular abnormalities.
- Molecular diagnosis guides therapeutic regimen and has prognostic implications in many of these entities.
- It therefore remains important that pathologists evaluating peripheral blood, bone marrow, and lymphoid tissue samples continue to be familiar with the spectrum of available molecular diagnostic techniques and be able to integrate their results with the findings of other ancillary studies.

1 Introduction

Infections are an important cause of morbidity and mortality in patients with neoplastic diseases. Infections may either coexist with malignancies posing diagnostic difficulties or may be complications of a treatment. The introduction of aggressive chemotherapeutic regimens, resulting in prolonged and profound neutropenia, promotes invasion by microorganisms. Most often, these infections are of a bacterial etiology. There are several factors like the primary disease, the degree of immunosuppression, the chemotherapeutic regimens used, hematopoietic stem cell transplantation (HSCT), etc. that predispose to certain patterns of infections. For example, candidemia is important in patients with prolonged neutropenia and mucosal damage. Infections with filamentous fungi like Aspergillus, develop in patients with prolonged and profound neutropenia. Herpes simplex infection may be reactivated in immunosuppressed patients with leukemia.

The current need is to provide accurate, rapid diagnosis of these infections and further guide clinicians on the management and prognosis. The clinical microbiologist and the microbiology laboratory both play a vital role in the management of neoplastic diseases. This highlights the need for a strong partnership between the treating clinician and the clinical microbiologist.

The initial evaluation requires three questions to be answered

1. Is the etiology of the illness microbial?
2. What is the identity of the microorganism?
3. What is the susceptibility profile of the microorganism?

The timely selection of an appropriate diagnostic test has a significant impact on the survival of patients.

Newer methodologies are more sensitive with a rapid turnaround time, but there are several challenges in the interpretation of results.

The current era of diagnostics is aided by several advances, including surrogate markers and molecular tools. The philosophy should be to integrate new technologies with conventional microbiology for the successful and accurate identification of microorganisms encountered in the laboratory.

2 Specimen Selection, Collection, and Processing

The quality of the results and their interpretation is entirely dependent on the choice and quality of specimens submitted to the laboratory for analysis. Health-care personnel collecting specimens should be aware of this and follow standard

protocols for collection and optimize the time of transportation to the laboratory.

There are three stages for laboratory tests

1. Preanalytical stage: This involves selection of the test, type of specimen to be collected for analysis, labeling, and transportation to the laboratory.
2. Analytical stage: The specimen sent is analyzed by the laboratory for the presence of specific microorganisms. The clinical microbiologist then interprets the results, in the context of the case, differentiating commensals, contaminants, and pathogens.
3. Postanalytical stage: The laboratory results are used by the treating clinician to determine the therapy, if any, to the patient.

The preanalytical stage is the most important stage in laboratory testing. If the wrong test is ordered, or the wrong specimen is collected, wrongly labeled, or improperly transported, then the results are affected and the treatment administered will be inappropriate.

The importance of specimen collection is often underestimated. There are several causes of fever with chills, and only a careful history and physical examination will result in the selection of an appropriate specimen. Both the method of specimen collection and the rapid transportation to the laboratory for testing are equally important. Some pathogenic microorganisms lose their viability and may not be recovered if the specimens are not appropriately transported and/or stored. Therefore, rapid transport of specimens is important for optimal accuracy of analytical results.

2.1 Direct Examination

Gross or macroscopic examination: Once a specimen is received in the laboratory, the first step is to evaluate its gross appearance. This often indicates the likely cause of infection. Infected specimens, namely, urine and cerebrospinal fluid, often appear cloudy due to the presence of white blood cells and microorganisms. Stools specimens may show worms like *Ascaris lumbricoides*. Pus samples from a cold abscess have a typical cheesy appearance. Infected specimens from the lower respiratory tract appear as “purulent” sputum specimens. The presence of visible blood should be noted.

Microscopic examination: This is rapid, easy-to-perform, inexpensive, and available round the clock. It is not as sensitive or specific as culture or some molecular tests but is useful in certain situations for a rapid diagnosis.

Wet mounts: The specimen is mixed with normal saline and viewed directly under a microscope. This tool is useful for the examination of genital secretions for parasites like *Trichomonas vaginalis* and the presence of yeast cells. Modifications with potassium hydroxide (10% KOH) are useful for the visualization of fungal mycelia from skin scrapings. The addition of India ink is used for the visualization of Cryptococcus and Calcofluor white, and a fluorescent stain can be used for the direct visualization of fungal mycelia in tissue specimens. Stool specimens can be screened for ova and cysts by direct examination with saline and 5% Lugol’s iodine.

Gram stain: This is the most frequently used stain in microbiology and serves as a rapid and easy-to-perform diagnostic tool. It differentiates bacteria based on their staining characteristics into Gram-positive (violet) and Gram-negative (pink) and based on their morphology into cocci or bacilli. This basic stain can be used directly on specimens like pus and sputum as an indicator of the type of infection. A pus sample showing Gram-positive cocci in clusters is an indication that this infection is caused by *Staphylococcus aureus*. A sputum sample with plenty of pus cells and Gram-positive diplococci, both intracellular and extracellular, indicates this pneumonia to be caused by *Streptococcus pneumonia*.

Staining of acid-fast organisms: Mycobacteria have a thick outer coat of mycolic acid, which is refractory to dyes like Gram stain. Stains like carbol fuchsin or auramine–rhodamine can form complexes with mycolic acid. These complexes are not washed out by acid alcohol. This characteristic is used for the identification of *Mycobacterium tuberculosis* in sputum and other specimens. Furthermore, modifications of this are used to identify organisms like *Nocardia* in specimens or from cultures and *Cryptosporidium parvum* with a special modification called the Kinyoun cold stain.

Direct fluorescent antibody stains: This is a rapid tool for the detection of viral antigens on infected cells from nasopharyngeal swabs for respiratory syncytial virus, Legionella infections, etc. This is frequently used for the detection of organisms that cannot be easily cultured (Figs. 1 and 2).

Diagnosis of agents from peripheral blood and tissue sections: Peripheral blood is the specimen of choice for the detection of Plasmodia, Babesia, trypanosomes, and microfilaria. Stained tissue sections can be used for the diagnosis of mycelial fungi, yeasts, Histoplasma, and *Sporothrix schenkii*. Parasites can also be visualized directly in sections like *Trichinella spiralis* and larvae and adult forms of parasites.

Antigen detection: A variety of tests are available for the detection of specific antigens of bacteria, viruses, fungi, and parasites. The test formats are either enzyme immunoassays or latex agglutination. Cryptococcus latex agglutination is a commonly used test in practice. Galactomannan assays and beta-D-glucan assays are enzyme immunoassays for the

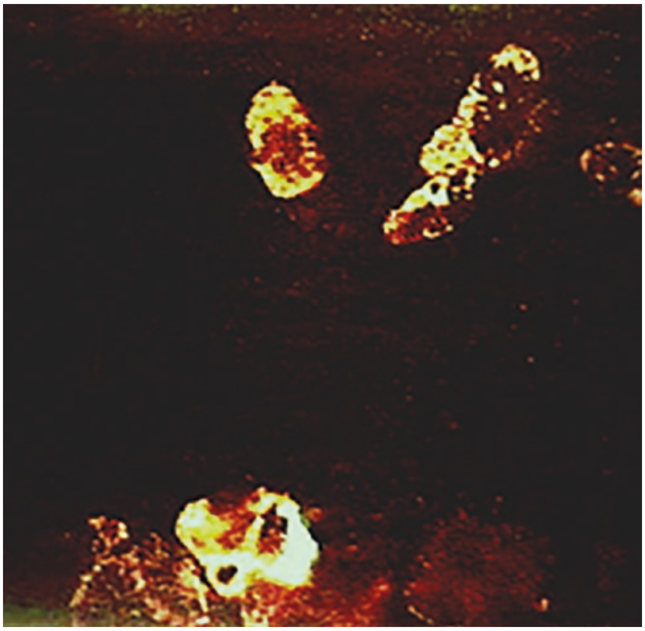

Fig. 1 RSV antigens in nasopharyngeal swabs

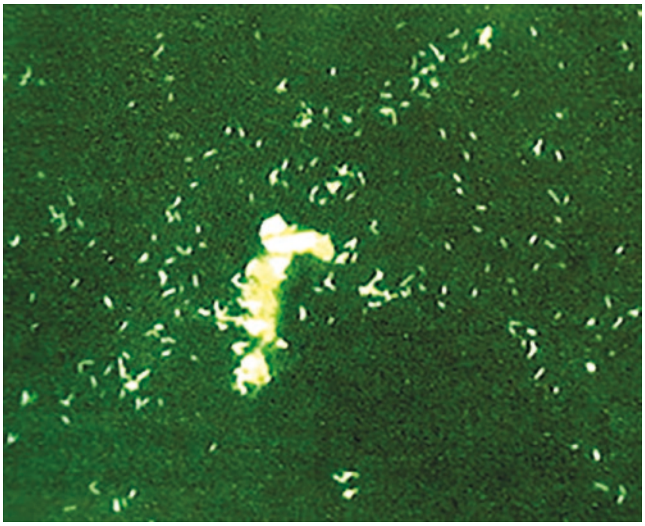

Fig. 2 *Legionella pneumophilia* by immunofluorescence

galactomannan antigen of Aspergillus and other fungi including *Pneumocystis jirovecii*, respectively.

2.2 Molecular Diagnostics

Molecular methods are now routinely incorporated into clinical microbiology, with a shift from conventional methods of microscopy and culture to rapid methods like antigen detection. However, clinicians need to be updated on available methods and, more importantly, on interpretation in the clinical context and the pitfalls.

A combination of classical techniques and new technologies is vital for the successful, accurate identification of all microorganisms encountered in the laboratory.

Polymerase chain reaction (PCR): PCR is best used when conventional clinical microbiological diagnostic procedures are inadequate, time-consuming, difficult, or when the organisms cannot be cultured. This functions as a molecular fingerprint to help identify microbes. Nested PCR increases the sensitivity and specificity of the conventional PCR. This tool has the greatest impact on clinical virology due to its increased sensitivity, specificity, and reduced turnaround time. This eliminates the time-consuming tasks of maintaining cell lines, immunostaining, and viral cultures. The test results assist in the early recognition of infections, directing and monitoring antiviral therapy.

Technological advances in automation from manual in-house to commercial Food and Drug Administration/in vitro diagnostic (FDA/IVD)-approved systems and the introduction of real-time PCR for quantitation and digital PCR has resulted in better utilization of this tool. Quantitation is essential for disease progression, prognosis, and response to antivirals for monitoring infections like human immunodeficiency virus (HIV), cytomegalovirus (CMV), Epstein–Barr (EBV), human herpes virus 6 (HHV6), and BK virus infections.

Sanger sequencing: The original method described in 1976 has the limitation of a single amplicon and has undergone modifications. Sequencing is used in diagnostic microbiology for the identification of microorganisms, detection of resistance mechanisms like extended spectrum beta lactamases (ESBL) and Methicillin resistant *Staphylococcus aureus* (MRSA), and detection of drug resistance.

Automation allows the reaction to be performed in a single tube with different fluorochromes for each base, and the resulting electropherogram is matched with the reference sequences of standard databases for identification.

Next-generation sequencing (NGS) and whole-genome sequencing (WGS): These are high-throughput methods that encompass several different technologies at a low cost.

NGS with amplicon sequencing is valuable for the prediction of oncogenic potential or antimicrobial resistance. It is useful for the identification of Mycobacteria and the prediction of resistance to anti-tubercular drugs, viz., rifampicin, isoniazid (INH), pyrazinamide, and ethambutol. Pyrosequencing is useful for epidemiological infections during outbreaks.

Mass spectrometry (MS): Matrix-assisted laser desorption/ionization time-of-flight MS (MALDI-TOF-MS) has been recently introduced to clinical laboratories for the identification of bacteria, Mycobacteria, including nontuberculous

Mycobacteria, yeasts, and fungi. This test requires growth of the organism and is low-cost, rapid, and takes about an hour for the results. It is used for the direct identification of organisms in positive blood cultures and urine specimens. There are ongoing studies for antimicrobial susceptibility testing.

Syndromic panel-based testing: A recent development has been the introduction of syndromic panels for testing in clinical microbiology laboratories. Commercial panels for the rapid detection of pathogens in positive blood cultures, respiratory specimens, gastrointestinal (GI) specimens, and central nervous system (CNS) infections are now available. These are multiplex tests that enable rapid diagnosis, allowing the timely management of infections. However, they require a thorough evaluation for clinical practice, proper selection, utilization, and interpretation.

Rapid testing of positive blood cultures: This is a multiplex PCR that detects organisms and resistance genes from positive blood culture bottles in 1–3 h. The disadvantages of this system are that there are fixed panels that do not cover all microorganisms and false-positive results are known. Hence, these are currently being used as "add-on" tests to conventional methods of blood culture.

Multiplex detection of respiratory pathogens: There are several FDA-approved multiplex panels that detect a range of viruses, including adenoviruses, coronaviruses, influenza viruses, parainfluenza viruses, and respiratory syncytial virus and bacteria like *Chlamydia pneumoniae* and *Mycoplasma pneumoniae*.

These tests are currently under evaluation for their clinical and economic impact. The major limitations are fixed panel tests, reduced sensitivity for some agents, inability to differentiate between colonization and infection, and possible missing of co-infections. The use of nasopharyngeal swabs as specimens for testing may result in missing lower respiratory tract infections, necessitating further procedures for the collection of bronchoalveolar lavages (BALs).

Prolonged shedding of some respiratory agents in immunocompromised patients requires interpretation in the clinical context.

Multiplex detection of GI pathogens: Panels that cover pathogens for diarrheal illnesses include bacteria like Campylobacter, Salmonella, Shigella, Vibrio, Yersinia, and *Escherichia coli*, viruses like norovirus, rotavirus, astrovirus, adenoviruses, and sapovirus, and parasites like Cryptosporidium, *Entamoeba histolytica*, and *Giardia lamblia*. This panel is of public health importance, and the ideal panel for testing is still unknown.

Multiplex testing for CNS infections: Panels include CMV, enterovirus, HSV 1 and 2, HHV6, and varicella zoster virus (VZV), bacteria including *E.coli*, *Haemophilus influenza*, Listeria, Neisseria, Streptococci, and Cryptococcus. The results of testing are available is less than 1 hour. This has been a recent introduction, and the results of evaluation studies are not available.

Molecular tests have been incorporated into routine diagnostics in oncology in the following areas

- Cytomegalovirus DNA testing is conducted weekly for patients undergoing bone marrow transplantation. This is performed by real-time PCR, for monitoring treatment with antivirals.
- Testing for hepatitis B infections for monitoring viral loads during therapy is now a routine practice. The technology is real-time quantitative PCR.
- Hepatitis C virus (HCV) infections are confirmed following a screen test with a positive result by reverse transcription-PCR (RT-PCR). Quantitation is carried out in HCV infections to determine the duration of antiviral treatment.
- Human papilloma virus (HPV) testing is used as a screening tool for the high-risk genotypes for cervical cancer. Several test systems are available, including E6 and E7 oncoprotein detection. The DNA by hybrid capture for screening 15 high-risk HPV types is an approved test. Real-time PCR and chip-based tests are also available for screening and genotyping.
- HIV RT-PCR is performed for HIV diagnostics and for monitoring viral loads during treatment of HIV infections.
- GeneXpert is a fully automated system that is used for the detection of *Mycobacterium tuberculosis* and rifampicin resistance in pulmonary and extrapulmonary samples. This is a rapid test that produces results within 2 hours.

Molecular diagnostics is a powerful tool; the results allow timely diagnosis and influence management decisions and treatment, but there are several unanswered questions listed below:

- What is the duration of DNA persistence after treatment?
- Does DNA persist even after eradication of microbes?
- What are the blood DNA levels after microbial lysis?
- Is bacterial RNA a better indicator of the current infection?
- How can PCR distinguish between colonization, latent infection, active infection, and relapsing infection?

In conclusion, there is a need for careful integration of what is technically feasible with what is clinically important because clinical microbiology is an "interpretative science."

2.3 General Guidelines for Specimen Processing for Bacterial and Fungal Culture

The specimens commonly sent for culture are blood, pus, respiratory tract secretions, urine, fecal specimens, cerebrospinal fluid, sterile body fluids like pleural fluid, ascitic fluid pericardial fluid, drain fluids, tissues, and biopsies sometimes collected under computed tomography (CT) or ultrasonogram (USG) guidance and catheters from intravascular sites. In some cases, specimens are processed quantitatively, for example, catheter tips are processed by the Maki's method, by rolling them three times on a culture plate. Urine and non-direct bronchoalveolar lavage (NDBAL) samples are also processed quantitatively. Specimens for mycobacterial and fungal culture need to be processed in special media, and the laboratory requires intimation to that effect. There are written guidelines for specimen collection, transportation, and rejection of inappropriately collected specimens. Specimens that are collected after hours should be sent in transport media. Oncology centers have some unique requirements and requests, which require discussion with the laboratory physician.

Culture: Culture is the commonly used technique for the detection of bacteria. The majority of human pathogens grow in 1–2 days of incubation. Mycobacteria are slow-growing and take nearly 3–4 weeks for the detection of growth. Mycelial fungi take at least 48 hours for visible growth. Longer incubation periods of 3 weeks are required for dimorphic fungi like Histoplasma. Some microorganisms are fastidious (organisms with highly complex growth requirements) and have special requirements like *Neisseria meningitis*, which requires carbon dioxide for optimum growth, and *Haemophilus influenza* and *Helicobacter pylori*, which require microaerophilic conditions for growth. Anaerobes require special collection systems, transportation, media, and growth conditions. Tissue samples need to be homogenized for processing. In patients with suspected zygomycosis, the tissues need to be carefully processed as this delicate fungus gets killed during processing. Appropriate processing of samples and recovery of etiological agents depend on the clinical details provided. This also decides the media used for processing. There are different media and growth conditions for bacteria, fastidious microorganisms, anaerobic bacteria, and fungi, including dimorphic fungi. The majority of microorganisms grow best at 37 °C; however, some clinically significant organisms require low temperatures (4 °C), whereas some grow at higher temperatures (42 °C). Some skin pathogens like dermatophytes grow better at 30 °C. Incubation temperatures therefore need to be modified depending on the suspected infection.

Media: The selection of media is dependent on the organisms to be isolated. Microorganisms have different nutritional requirements. The basic medium used for Gram-positive organisms is sheep blood agar. This allows the visualization of hemolysis, which differentiates Streptococci, Staphylococci, etc. The enrichment with blood allows the growth of many fastidious organisms. This is heated to chocolate agar for the growth of Neisseria and, when supplemented with growth factors, is used to isolate *Haemophilus influenzae*. Most Gram-negative rods grow on MacConkey agar, which is a selective medium with crystal violet and bile salts that inhibit some Gram-positives. Special isolation media are required for organisms like Legionella and Bordetella, whereas the recovery of stool pathogens like Shigella and Salmonella requires selective media (Figs. 3 and 4).

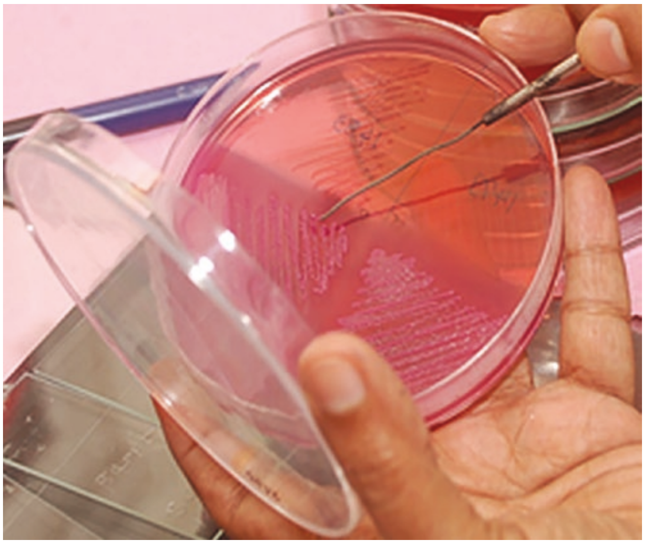

Fig. 3 Growth in MacConkey's medium

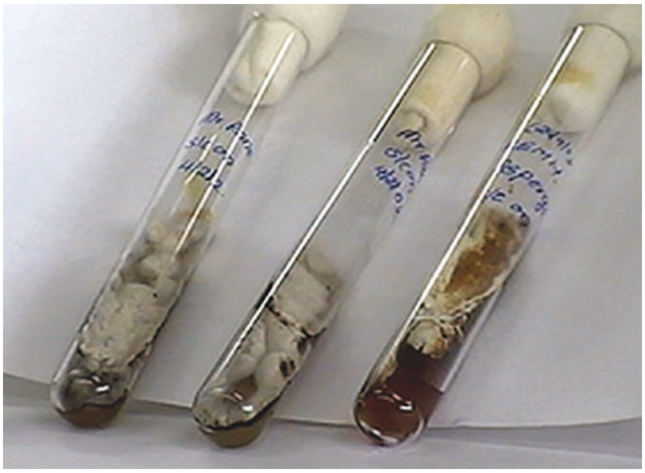

Fig. 4 Growth of mycelial fungi

Mycobacterial cultures are performed after decontamination of specimens in a Lowenstein–Jensen medium and in liquid culture systems (Fig. 5). There are several commercial systems available for the detection and identification of *Mycobacterium tuberculosis.* Most laboratories use molecular tools for the detection of Mycobacteria. In India, many centers still use manual methods for detection.

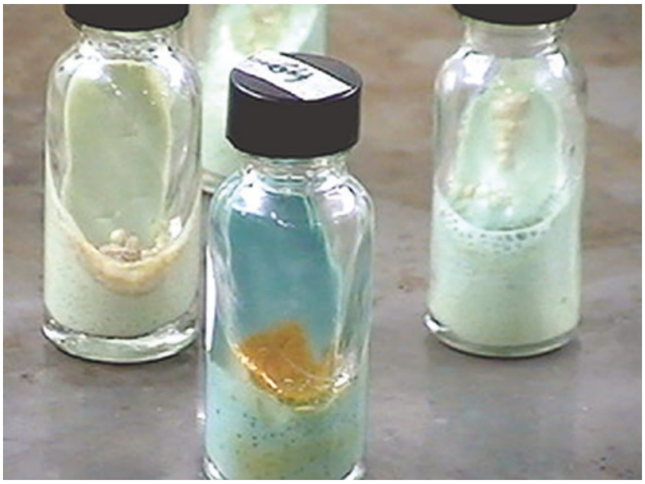

Fig. 5 Growth of Mycobacteria in a Lowenstein–Jensen medium

3 Detection and Identification Methods

Organisms are isolated as growth of colonies on agar plates. These can be identified as pathogens once their significance is established, and they are differentiated from the resident microbiota and colonizers. The appearance of colonies often indicates the identity of an organism. Growth on blood agar with different types of hemolyses is used to identify Streptococci and Staphylococci. Streptococci are further identified based on their susceptibility to differentiation discs of optochin and bacitracin. Optochin-susceptible alpha-hemolytic organisms are presumptively identified as *Streptococcus pneumonia.* The growth of *Pseudomonas aeruginosa* is identified by the green pigment and non-lactose fermenting colonies. Flow charts are available for the identification of bacteria and yeasts based on colony morphology, staining characteristics, motility, pigment production, etc. The identification is confirmed by biochemical tests. Some organisms like the Salmonella species are confirmed by serology and agglutination with specific antisera. Manual biochemical identifications are the gold standard.

Manual identification of yeasts follows a flow chart based on colony characteristics and basic tests like germ tube and urease. The identification is based on carbohydrate assimilation and fermentation reactions, which are matched with standard classifications like the Ahearn's classification.

Identification of mycelial fungi is based on growth characteristics, pigment production and its characteristics, followed by slide culture to determine the pattern of sporulation, which identifies the fungus.

Dimorphic fungi like *Histoplasma capsulatum* are detected in tissues and blood in the yeast form. When they are cultured at 30 °C, they grow in the mycelial form. Confirmation of the identity is possible only after they are converted from the yeast to the mycelial phase in blood-containing media, incubated at 37 °C. It takes several weeks of serial subculture for this conversion from the mycelial to yeast form.

Identification of microorganisms at the species level is important because it helps determine the role that an organism may play in the patient's disease process and influences clinical management.

There are several automated systems available for identification of bacteria and yeasts. Their major disadvantage is they do not take into account morphological characteristics like pigment production, colony morphology, motility, etc. Molecular methods for identification, including MALDI-TOF-MS, have already been discussed.

Molecular epidemiological tools are used for typing organisms during outbreaks.

4 Antimicrobial Susceptibility Testing

Antimicrobial susceptibility testing is performed on rapidly growing bacteria once the role of the organism in the disease process is established. There are several methods for testing. The commonly used method is the Kirby–Bauer disc diffusion method (Fig. 6). The results of this accurately predict resistance to antimicrobials. If an antimicrobial is reported as susceptible, then it indicates a likelihood of response to that antimicrobial. Standard interpretative guidelines are used to determine and interpret the results of testing. These may be from the Clinical and Laboratory Standards Institute (CLSI) or the European Committee on Antimicrobial Susceptibility Testing (EUCAST). Fastidious organisms require Mueller Hinton with a blood supplement for the susceptibility testing.

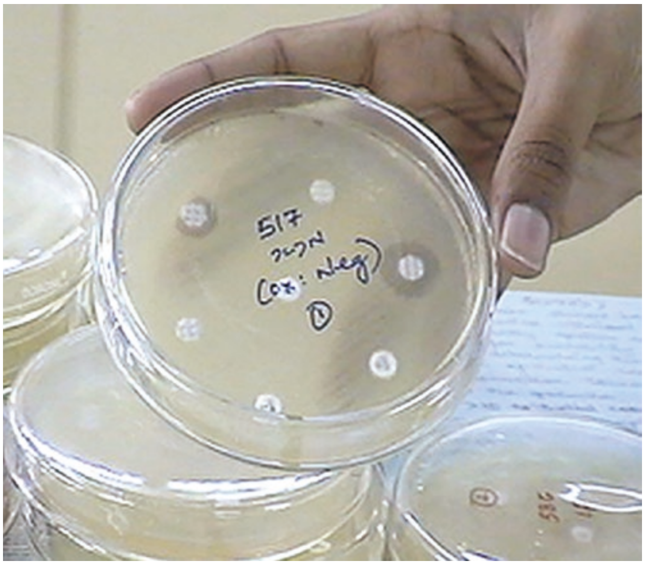

Fig. 6 Kirby–Bauer disc diffusion method

Automated systems that determine the minimum inhibitory concentration of the antimicrobials are increasingly being used in clinical practice. A popularly used method for minimum inhibitory concentration (MIC) testing is the "E" test, a plastic strip that contains a gradient of the antimicrobial (Fig. 7). This strip is applied to a lawn culture of the organism on an agar plate. The point where the zone of inhibition intersects with the strip is the MIC of the antimicrobial tested for the organism.

Micro-broth dilution methods are the standard for many antimicrobials and for antifungal susceptibility testing of yeasts and molds (Fig. 8). Antifungal susceptibility testing methods are now the standard, and interpretative criteria for many antifungals are available. Automated systems like Vitek 2™, Phoenix™, etc. have provision for antifungal susceptibility testing of yeasts. A commercial system called Sensititre™ can be used for antifungal susceptibility testing of molds. In clinical practice, MIC values are used for decisions on the choice of antimicrobials and have become a part of the reporting practice in clinical microbiology.

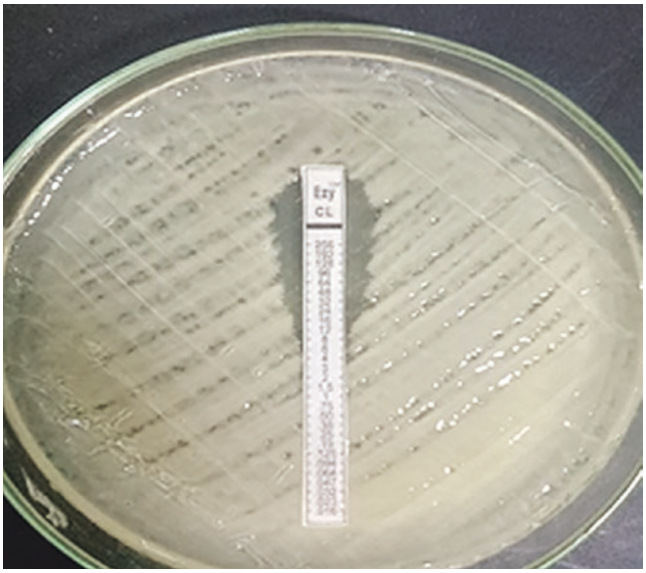

Fig. 7 An "E" test

Susceptibility testing for *Mycobacterium tuberculosis* can be performed in automated systems or manually by the absolute concentration or resistance ratio methods (Fig. 9). Basic laboratories do not perform identification or susceptibility testing of Mycobacteria. Methods are available for the susceptibility testing of nontuberculous Mycobacteria.

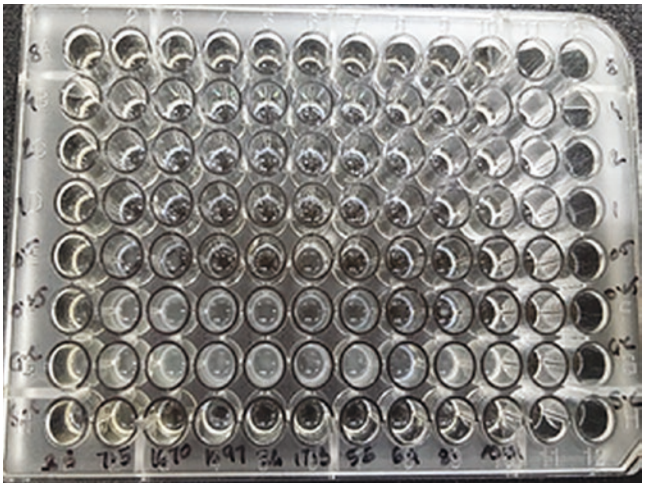

Fig. 8 The micro-broth dilution method for MIC testing

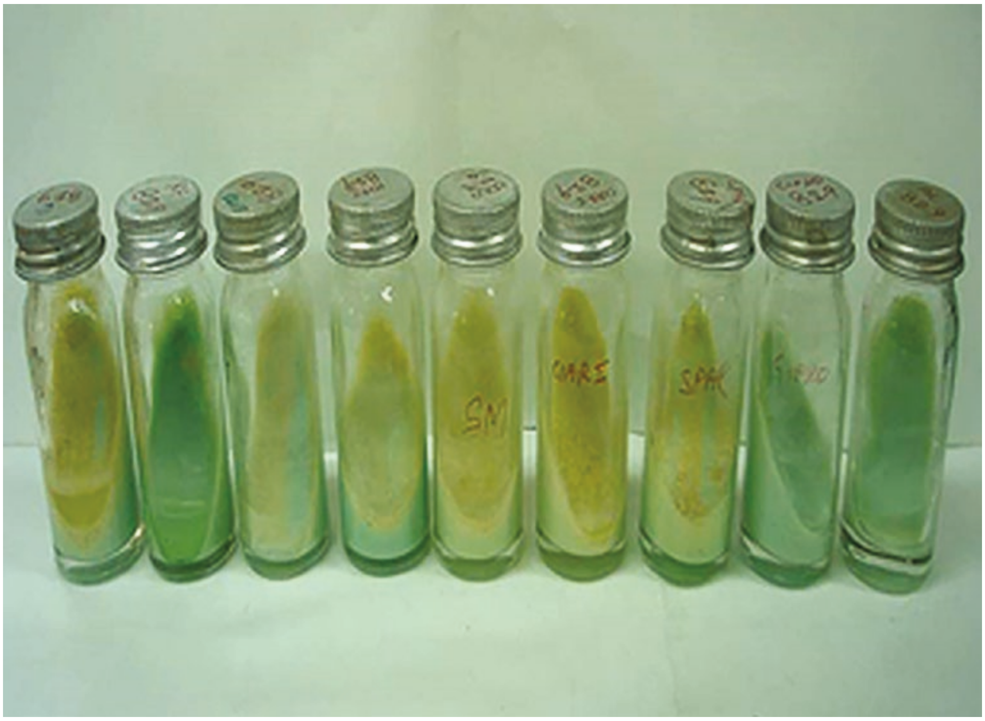
Fig. 9 Susceptibility testing for *Mycobacterium tuberculosis*. The absolute concentration method



5 Specific Recommendations for Major Infections

5.1 The Respiratory Tract

Respiratory tract cultures should be interpreted along with clinical and radiological findings. In non-neutropenic patients, the presence of significant numbers of pus cells (>25/lpf) in a Gram stain of the specimen is a useful indicator of an infection. If the results of culture are considered in isolation, then one ends up treating "bacteria" rather than an infection. Moreover, hospitalized patients, particularly critically ill patients, get colonized with hospital flora within 24 hours of hospitalization. The laboratory processes only specimens that are suggestive and representative of the lower respiratory tract. In case a patient is neutropenic, this needs to be indicated. Fungi like Candida are part of the normal flora and are not reported. It is essential to provide clinical information to facilitate appropriate processing and reporting.

Direct examination of samples is conducted for infections like Cryptococcus and acid-fast bacilli.

In critically ill patients, bronchoalveolar lavages or non-direct bronchoalveolar lavages (NDBALs) are sent. NDBAL samples are processed quantitatively. In fungal infections of the lung, a guided biopsy provides a tissue diagnosis. Tissues can be examined directly by the calcofluor stain for the demonstration of fungal mycelia.

5.2 Tissue Diagnosis

An oncology patient poses a diagnostic dilemma in several situations. Lung infections are a typical example of such a situation. It is often difficult to differentiate between a malignancy alone, a malignancy with an infection, or an infection alone.

Invasive tests may not be possible, and one may have to depend on specimens like bronchoalveolar lavages (BALs). Bronchoscopy, therefore, has a definitive role to play. A good BAL can thus clinch the diagnosis.

On rare occasions, it may be possible to perform an open lung biopsy. Many a times, material from suspicious lesions is collected only for histopathology (HP). The microbiologist will then have to depend on special stains and his/her own skills to provide a diagnosis of an infectious agent. It is possible to indicate the nature of the agent on histopathology; however, speciation and confirmation of the identity is only possible on culture. This is particularly so in the case of fungal pathogens when the histology section shows the presence of "fungal mycelia" which is a morphological diagnosis.

Some agents like Cryptococci can be diagnosed with a reasonable level of confidence on HP alone.

Cultures, however, remain the gold standard with all agents of infectious diseases. Lymph node lesions are another difficult situation where establishing the etiology of an infectious agent in the absence of a malignancy/metastasis is often elusive.

In cases with mycobacterial lymphadenopathy, direct visualization of acid-fast organisms is often negative. However, the majority of the aspirates/tissues in culture are known to yield positive results.

5.3 Fungal Infections

Fungal infections pose a major threat to cancer patients and remain a diagnostic dilemma for laboratories. A report of fungemia from the laboratory, i.e., the isolation of a fungus from a blood culture, should always be respected and treated with due concern.

Morphological diagnosis of a fungal infection should be supplemented with cultures. Not all fungi are responsive to antifungals. Moreover, antifungal drug resistance needs to be accounted for. Thus, diagnosis of a fungal infection in a cancer patient consists of a high index of clinical suspicion in patients with prolonged and profound neutropenia not responding to antibacterial agents.

Rapid assays for the detection of fungal antigens, galactomannan and beta-D-glucan assays, and nucleic acids by polymerase chain reactions (PCR) are also available for some common agents like yeasts and Aspergillus.

5.4 Blood Stream Infections

Blood culture is the most meaningful investigation, particularly in the febrile neutropenic patient. The recovery of microorganisms from blood in a bacteremic patient depends on the timing of the culture, ongoing antibiotics, method of collection, and method of processing.

It is mandatory to take aseptic precautions during collection; otherwise, one will isolate the contaminating skin flora.

There are several automated systems for the incubation of blood cultures, which reduce the time to detection of microbial growth in blood. Once there is a positive growth signal, the Gram stain indicates the type of organism, and direct susceptibility testing and identification can be performed. This reduces the reporting time by 12–24 hours. Separate media are available for bacteria, anaerobes, fungi, and Mycobacteria.

In patients with indwelling catheters, quantitative cultures from the peripheral vein and catheter are helpful in evaluating whether the catheter is a source of bacteremia. This can be proven if the same microorganism is isolated from the peripheral vein and the catheter with the pathogen growth at least two hours earlier from the catheter in paired blood cultures.

A blood culture yielding fungal growth is a certain test of a systemic fungal infection in a patient.

For detection of Aspergillus in blood, at least two (each 10 mL) aerobic blood cultures should be cultivated. If patients have a central venous access device, then cultures should be obtained through the catheter as well. In blood cultures, the chances of isolating yeasts are higher, detecting Candida species. in up to 60% of all fungemias within 2–5 days. Blood cultures have an extremely poor yield in patients with invasive aspergillosis, and the results are often negative even in patients with disseminated disease. Thus, a lack of positive culture does not rule out the diagnosis of invasive aspergillosis.

5.5 The Central Nervous System

Specimens of cerebrospinal fluid should be sent immediately to the laboratory. A direct examination of the sample by Gram stain indicates the likely organism in a case of bacterial meningitis. Examination with India ink showing negative staining of yeasts indicates cryptococcal meningitis. These samples can be processed for tests like adenosine deaminase for a presumptive diagnosis of tubercular meningitis.

5.6 The Urinary Tract

Urine samples must be transported to the laboratory within 3 hours of collection. The sample must be a mid-stream, clean-catch specimen, to avoid the contaminating genital flora. Urine is processed quantitatively, and only samples showing a significant number of polymorphs are processed for culture and those showing a colony count >10^5 cfu/mL, indicating significant bacteriuria, are reported.

5.7 Gastrointestinal Specimens

The commonest specimen is stool. Biopsies from the gastric mucosa are sent for cultures for *Helicobacter pylori.* A rapid urease test and Gram stain are the rapid tests for a presumptive diagnosis of *H. pylori*. Cultures are performed in special media and it takes 72 hours for the growth.

Stool specimens, which are watery or show pus cells, are processed for cultures for enteric pathogens. Surveillance cultures are performed for colonization with multidrug-resistant organisms to predict future episodes of infection and empiric treatment of febrile episodes.

6 Conclusions

There is a need for rapid and accurate diagnosis of infections in oncology, at the species level. The trend is changing and the pattern is different during the phases of treatment. Several emerging, new, and reemerging organisms are being documented as etiological agents. There is a need for tracking pathogens and susceptibilities. Multidrug-resistant isolates are on the rise. Antimicrobial resistance should be recognized as a serious problem and efforts taken to halt its growth. Given the relationship between antimicrobial resistance and use, antimicrobial stewardship is the logical first step to control antimicrobial resistance. Health-care facilities should decide on appropriate antimicrobial stewardship programs and diagnostic stewardship programs to pave the way for better outcomes.

Imaging in Oncology

Seema A. Kembhavi, Palak Bhavesh Thakkar (Popat),
and Meenakshi H. Thakur

1 Introduction

Imaging is a rapidly advancing field of medicine and is an integral part of cancer care. From its advent with a mere radiograph, an image formed by the projection of X-rays having passed through a part of the body, its role has exponentially gained momentum with numerous modalities being invented, such as ultrasonography (USG), which uses the principles of interaction of an ultrasound (US) beam with tissues in the body as it transmits through it, computerized tomography (CT), which uses a narrow beam of X-rays and an array of detectors, and magnetic resonance imaging (MRI), which is based on the effects of radio frequency and magnetism on the protons in the body. The radiograph itself has also gone through major technological evolution through computerization and digitization, leading to computerized radiography and digital radiography, thus easing the processing of acquired images, archiving data, and aiding in better imaging interpretation [1].

Imaging plays a role in detection, diagnosis, and staging as well as monitoring during treatment (response evaluation) and surveillance imaging. In the plethora of options available, it is important to understand which modality has to be used to answer a specific question at each step. In most cancers, imaging is quintessential prior to surgery and helps in planning exigent surgical procedures.

Each type of cancer has imaging integrated in its own specific way; however, in this chapter, we have disintegrated imaging in terms of modalities and briefly described the utility of each modality in modern cancer care.

2 Indications for Conventional Radiography in Oncology

Some notable indications for radiography in oncology are provided in Table 1. The most commonly performed radiography is that of the chest for evaluation of metastatic disease, anesthesia fitness, and pulmonary complications during treatment of cancer like infections, treatment-related toxicities, etc. Other indications for radiography are whole-body skeletal survey for multiple myeloma, spine radiographs for metastatic workup, and detecting the cause of backache/radiculopathy. To date, a radiograph of the bones remains the first and the most important investigation in the diagnosis of osseous lesions. Quite often, a radiograph is a modality to evaluate focal equivocal abnormalities that are detected on a bone scan, and it can help distinguish degenerative or metabolic abnormalities from neoplastic processes.

An orthopantomogram (OPG) is a special tomographic radiograph for the jaw, which is indicated in oncology for ruling out caries prior to initiation of radiotherapy for oral cancers and for evaluation of suspected osteoradionecrosis of the mandible.

Bedside radiographs constitute an important adjunct to patient management. These are useful for tracking the positions of lines and tubes in the body, the quantum of fluid

Table 1 Common indications of conventional radiography in oncology

Type of radiograph	Indications
Extremity and skeletal radiography	Detection of the pathology of the skeletal system such as primary bone tumor, secondary metastatic disease in bones, and pathological fractures (Fig. 1a)
Chest X-ray	Identification of lung diseases such as pneumonia, lung cancer, pulmonary edema, and metastatic disease in the lungs (Fig. 1b)
Abdominal X-ray	Detection of bowel (or intestinal) obstruction, free air (from visceral perforations) and organomegaly, abnormal calcifications, etc.

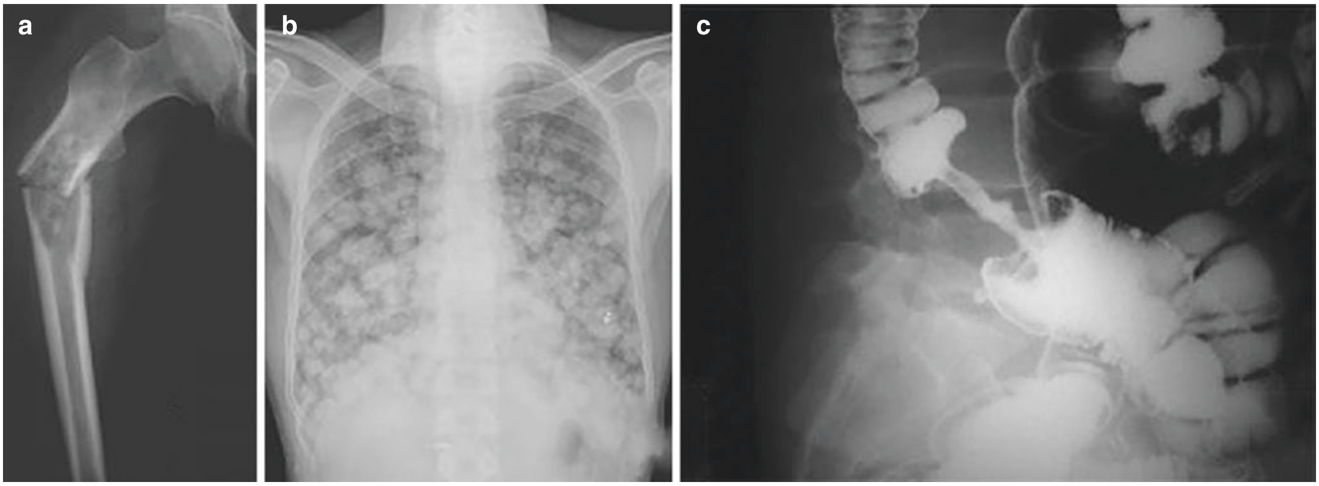

Fig. 1 (**a**) A radiograph of the right hip showing a pathological fracture in the proximal diaphysis of the right femur in an underlying expansile primary bone lesion. (**b**) A chest radiograph showing multiple canon ball opacities in the bilateral lung parenchyma (lung metastases). (**c**) Barium enema showing apple core deformity suggestive of colon cancer

collections such as effusions, and iatrogenic pneumothorax and iatrogenic emphysema. These also help in evaluating patients with acute abdominal pain, suspected to have intestinal obstruction.

Thus, despite the extensive use of cross-sectional imaging, a radiograph remains the persistent companion of nearly every patient in the oncology hospital.

3 Fluoroscopy and Contrast Studies

Fluoroscopy is another important technique in radiography, which is used to obtain real-time images of the internal structures of a patient with the use of radiographic contrast media to opacify the organs. Both the contrast media and its route of administration depend on the investigation. For example, oral administration outlines the lumen of the gastrointestinal tract (GIT), intravenous administration can delineate the kidneys, ureter, and bladder, the vascular tree can be delineated by intravascular (venous/arterial) administration, etc. It is now of immeasurable benefit in interventional radiology with its progress to image intensification and digital subtraction.

In the modern world of imaging, with the advent of newer modalities like CT scanning and MRI, the number and indications for fluoroscopic studies have significantly reduced (Table 2). However, there are few indications where these modalities may suffice for both diagnosis and treatment such as screening of cancers of the upper GIT and esophageal stent placement. When densities of the adjacent tissues are similar, a contrast agent is used to differentiate the surrounding structures. Structures typically requiring contrast instillation constitute the gastrointestinal and genitourinary system. Commonly used contrast agents are barium solution and water-soluble iodinated/noniodinated contrast agents. Barium is best used to visualize the gastrointestinal system; however, in certain conditions, there are some variations (see Table 2) [2].

Gas or air is also used for procedures like barium enema and loopograms to achieve double contrast and better delineation of the mucosa. If a bowel perforation or a leak is suspected, a water-soluble contrast agent is recommended because barium, if leaked, may cause barium peritonitis with sequelae of possible fibrosis/adhesions and small bowel obstruction. It is important to remember that in suspected cases of obstruction, barium enema is contraindicated as it may lead to barium impaction and further aggravate obstruction. On the other hand, in suspected cases of tracheoesophageal fistula or esophageal leaks, barium should be used rather than a water-soluble contrast agent as the contrast media can cause chemical irritation, whereas barium may not cause barium pneumonitis, if leaked in small quantity [2].

For non-gastrointestinal (GI) studies, iodine-based contrast agents are used. Certain sites in the body, however, cannot use these agents, such as the spinal canal for myelography (risk of neurotoxicity) or bronchial tree (risk of pulmonary edema). Nonionic contrast agents can be low-osmolar or iso-osmolar. Newer nonionic contrast agents have fewer adverse effects, are routinely used in most institutions, and are the first choice of contrast for pediatric and nephrology patients, the elderly, chronic diabetics, or for patients with borderline serum creatinine values [3].

Table 2 Common fluoroscopic studies with a contrast agent: indications and preparation

Region of interest	Study	Contrast agent	Indication	Preparation
Pharynx/esophagus	Barium swallow	Barium	• Stricture • Dysphagia • Hiatus hernia • Fistula • Diverticula • Inability to pass through an endoscope	In all, 6–8 h fasting Can have clear liquid
Stomach/duodenum	Barium meal	Barium	• Gastric ulcers • Gastric reflux • Tumors • Stricture • Diverticula	Overnight fasting
Small bowel loops	Barium meal follow through	Barium	Stricture Inflammatory/infective enteritis Diverticular disease Tumors	Overnight fasting Laxative—gut preparation
	Small bowel enema	Barium+ methylcellulose/ water	Precise localization of strictures Diverticular disease Enteritis Growth	
Large bowel loops	Barium enema (Fig. 1c)	Barium and air	Evaluation of the colon and rectum for strictures	Overnight fasting Laxative—gut preparation
Loopogram	Distal bowel loop	Water-soluble contrast or diluted barium	Pre-stoma closure to check the patency of the distal bowel and perforation	Nothing specific
Intravenous pyelography (IVP)	Kidneys; ureters	Water-soluble contrast	Ureteric obstruction Preoperative ureter mapping Postoperative ureteric leak Synchronous transitional cell carcinoma (TCC) with the bladder	Fasting 4–6 h Laxative—gut preparation
Micturating cystourethrography (MCU)	Urinary bladder Urethra	Water-soluble contrast	Postoperative evaluation Bladder outlet obstruction Hematuria Urethral stricture Recurrent urinary tract infection (UTI)	Nothing specific
Ascending urethrography	Urethra	Water-soluble contrast	Post-surgery Diverticulum, strictures Fistula Congenital anomalies	Nothing specific
Sialography	Salivary gland duct	Water-soluble contrast	• Obstruction • Ductal pattern • Post-radiotherapy • Functional integrity of glands	Nothing specific
Lymphangiography	Lymphatic system	Water-soluble contrast	Postoperative chyle leak Lymphatic obstruction	Nothing specific
Myelography	CSF space	Water-soluble contrast	Postoperative in case of artifacts on CT scan and MRI	Fasting 4 h

Special situation and preferred contrast:

- Esophageal perforation: water-soluble contrast
- Aspiration/fistula: barium or iso-osmolar water-soluble contrast
- Stomach/small and large bowel perforation: water-soluble contrast

4 Mammography

Mammography is a special low-dose radiography technique for evaluation of the breast tissue. The normal breast tissue consists of fibroglandular parenchyma and fat in varying proportions. Abnormalities in the breasts present primarily in the form of a mass lesion, microcalcifications, architectural distortion, or asymmetric density (Fig. 2). Microcalcifications that are detected on mammograms are less than a millimeter in size, and visualizing one from another requires an imaging technique, which has a high spatial resolution. The visual contrast between a normal and abnormal tissue varies from high to low depending upon the abnormality, e.g., microcalcifications are more radiopaque than the normal parenchyma but the lesions presenting as asymmetric densities or architectural distortions are not. Hence, this imaging technique has to have high contrast as well. These factors and the need to evaluate a superficial soft organ makes the mammography unit distinct from other radiography systems.

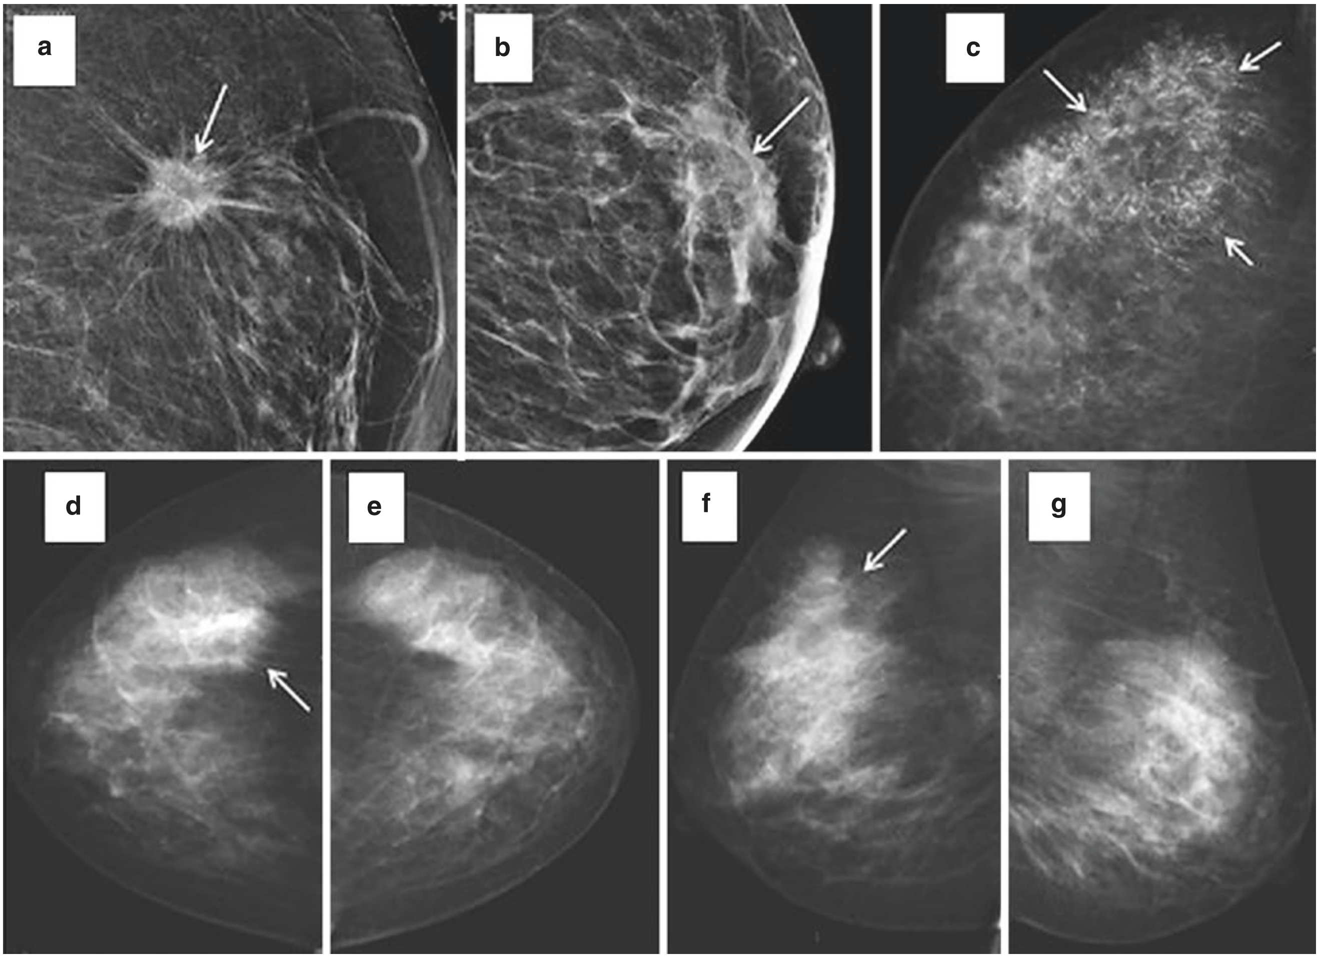

Fig. 2 Types of manifestations of breast cancer on mammograms. (**a**) A classic spiculated mass with microcalcifications (arrow). (**b**) An area of architectural distortion (arrow). (**c**) Regional branching pleomorphic microcalcifications (outer limits marked by arrows). (**d**–**g**) Different mammographic views of the right and left breasts of a patient showing asymmetric increased density in the right upper outer quadrant (**d**, **f**) marked by arrows

Today, mammography machines are available in screen film or analogue form and in digital systems. The advantage of the latter technique lies in improved dynamic range and contrast characteristics apart from the usual advantages of a digital technique like soft copy display, post-processing, transportability, and reduced rate of repeat radiographs for bad exposures. As such, a direct comparison of two techniques shows that the overall diagnostic accuracy of digital and film mammography for screening for breast cancer is similar, but digital mammography is more accurate in women under the age of 50 years, in women with dense breasts, and in premenopausal or perimenopausal women [4]. Digital breast tomosynthesis has been a recent modification in digital mammography, which allows multiple slices of the breast to be taken, like a CT scanner, thus reducing the problem of superimposition of tissues. This potentially helps in reducing recall rates and improving the cancer detection rate, but its benefit in terms of reduced mortality is not yet proven [5, 6]. Dual-energy subtraction and contrast-enhanced mammography are also advances in the mammography technique, which are being evaluated for use in clinical settings.

Mammography is performed in two scenarios: screening and diagnosis. Structured screening mammography programs are not available in India. Some earlier studies have shown an overall 15% reduction in breast cancer-related mortality (irrespective of the age of the patient) [7]. This comes at a cost of 30% in overdiagnosis and overtreatment. Currently, screening is offered to women who seek medical attention or to those who are at a high risk for breast cancer. The screening mammography units generally function independently from hospitals, and these mammograms are obtained in healthy women using two projections per breast and the studies are usually double read in batches. The women are then recalled if required for additional views or an ultrasound. Diagnostic mammograms are performed for women with signs and symptoms related to breast pathology. Indications include any clinical suspicion of a malignancy like a palpable lump, single-duct spontaneous nipple discharge, or nodularity/thickening. Often, additional views are obtained for suspected abnormalities, and an ultrasound may be performed for correlation, especially in women with dense breasts.

Mammography units are also used for performing guided interventions like stereotactic and tomosynthesis guided biopsies, hook-wire localizations, etc., for non-palpable lesions detected on mammograms and enhancing lesions detected only on contrast enhanced mammograms.

Standardized reporting formats like BI-RADS (Breast Imaging-Reporting and Data System) proposed by the American College of Radiology (ACR) have made a huge contribution in better acceptance of this modality and have paved the way for developing similar standardized formats for other organs like the prostate, liver, and thyroid.

5 Ultrasonography (USG) in Oncology

The advantages of USG are several: it is a quick study requiring almost no preparation, is also a "real-time evaluation" (also valuable for US-guided interventions like aspirations, biopsies, or injections) that is free of ionizing radiation, is widely available, and is portable. It is also relatively inexpensive compared to other modes of investigation. The biggest disadvantage of USG lies in the fact that it is operator-dependent. The documentation of abnormalities hence depends on the ability of the person performing the USG, and this cannot be subjected to review like radiographs or the cross-sectional modalities we are going to discuss later in this chapter.

Ultrasound is often the first investigation of choice when any abdominal mass/lesion is suspected. It helps in ruling out any developmental abnormalities, typically in children, or any functional cause that can mislead a clinician like an obstructed bladder mimicking a mass. It can also help in identifying masses and ordering the most suitable next line of investigations. It is also the first investigation for any small soft part imaging, like orbit, thyroid (Fig. 3), scrotum, soft tissue lesions of the limbs, and the breasts in younger women or in women with dense breasts on mammography. A real-time evaluation in combination with small maneuvers, like making the patient change dependent positions and combining it with Doppler, results in improved characterization of lesions.

The resolution offered by intra-cavitary USG like TVS (transvaginal ultrasound) or TRUS (transrectal ultrasound) makes US superior to CT scanning for characterization of uterine/pelvic lesions and the prostate.

Doppler evaluation for suspected deep or superficial venous thrombosis, suspected vaso-occlusive disease, problem solving for encasement versus contact between mass and major vessels, etc. are essential indications for ultrasound.

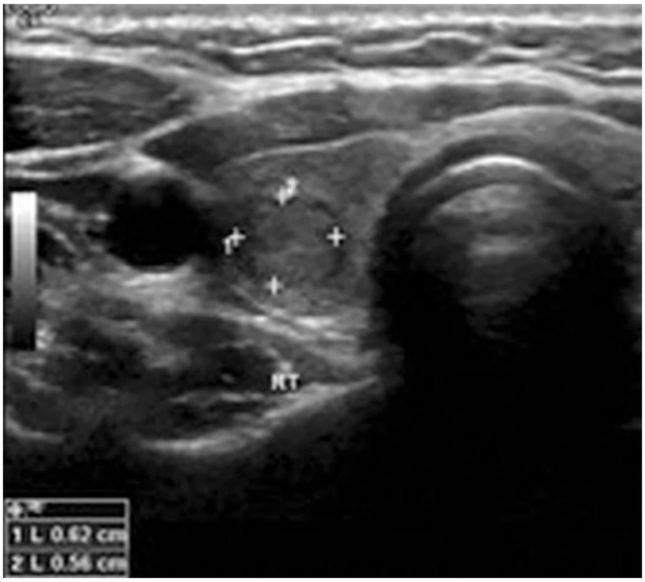

Fig. 3 Ultrasound of thyroid shows a circumscribed isoechoic nodule (bordered by + cursors) with a thin dark peripheral halo in the thyroid lobe on the right side of neck suggestive of a benign nodule

US is often performed for abdominal oncological emergencies like suspected torsion, tumor rupture, neutropenic colitis/typhlitis, evaluation of postoperative collections, etc.

Ultrasound is also the preferred modality for performing image-guided procedures like fine needle aspiration cytology (FNAC)/biopsies, drainage procedures like pleural or ascitic taps, pigtail placement in infected cavities/collections, etc.

Like portable radiographs, portable or bedside USG has become a part of standard of care in monitoring critical or sick patients in the intensive care unit (ICU).

6 Computed Tomography in Oncology

CT scanning is often considered as a workhorse of the oncological imaging department. It is not only used for diagnosis but also for staging of disease, assessing resectability, monitoring response to therapy, and in the follow-up after treatment. The important indications are displayed in Table 3.

CT angiography provides information on vascular involvement and preoperative vessel mapping, for detecting bleeders and thrombus. CT can also be used for guiding therapeutic procedures. Due to its multi-planar capability and recent advancement of CT softwares, various new applications can be obtained, which are shown in Table 4.

Table 3 Region-specific indications, area of coverage, and specific precautions/preparations for CT scanning

Region	Area of coverage	Indications
CT head (brain)	From the vertex to the base of the skull • Non-contrast scans • Contrast-enhanced scans	1. For diagnosis and follow-up of brain tumors and metastases (MRI is more accurate) 2. Acute intracranial hemorrhage and infarct 3. Effective in the detection of bone erosion 4. High Resolution Computed Tomography (HRCT) temporal bone for lesions involving the middle and inner ear along with involvement of the facial nerve pathway 5. Optimal visualization of the skull base foramina 6. Diagnosis and follow-up in patients with hydrocephalus
CT head and neck	From the skull base to the lung apices (should be covered up to the arch of the aorta if CT angiography of the neck is requested or if vocal cord palsy is being investigated) • Non-contrast scans (select indications) • Contrast-enhanced scans	Staging of tumors of 1. The nasal cavity and paranasal sinuses (MRI is preferred for perineural spread and to distinguish between tumor and secretions) 2. Pharynx (MRI is preferred for the nasopharynx) 3. Gingiva and buccal mucosa, specially for evaluating the mandible 4. Floor of the mouth and tongue (MRI is more accurate) 5. Orbital tumors 6. External ear evaluation 7. Salivary glands (MRI is preferred) 8. Larynx and hypopharynx 9. Thyroid and parathyroid glands 10. Upper trachea 11. Parapharyngeal masses (paragangliomas and schwannomas) 12. Bony tumors of the mandible, maxilla, and hyoid bones
CT thorax	From the nape of the neck up to the costophrenic recess (lower part) • Non-contrast scans • Contrast-enhanced scans	Detection, staging, and follow-up of tumors of 1. The lung (MRI is preferred in superior sulcus tumors) 2. Esophagus 3. Pleural tumors 4. Mediastinal masses 5. Breast masses 6. Rare tumors of the heart, aorta, and inferior vena cava (IVC) Detection and characterization of the mediastinal, hilar, or axillary adenopathy in cases of known malignancy Detection and characterization of the skeletal lesions (ribs, vertebrae, sternum, clavicle) Detection and follow-up of lung metastases Infective lung pathologies (patients on chemotherapy are prone to fungal pneumonia) CT bronchoscopy is a noninvasive technique to get virtual pictures of the airways Postoperative esophageal/anastomosis leak Diagnosis and follow-up of pleural/pericardial effusions
CT abdomen and pelvis	• From the dome of the diaphragm to the ischial tuberosities • Non-contrast scans followed by contrast-enhanced CT scans	Detection, staging, and follow-up of tumors of 1. Liver 2. Gall bladder and biliary tract 3. Pancreas and spleen 4. Stomach, small and large bowel (including GISTs and neuroendocrine tumors) 5. Rectum and anal canal 6. Prostate and seminal vesicles 7. Uterus, cervix, vagina, and vulva (MRI pelvis is more accurate for local evaluation for 5, 6, and 7) 8. Kidneys, ureters, urinary bladder, and urethra 9. Peritoneal masses 10. Retroperitoneal masses 11. Bone neoplasms and metastases (vertebrae, pelvic bones, proximal femora) Diagnosis and follow-up of secondaries in the liver, spleen, retroperitoneum, and peritoneum Diagnosis and follow-up of ascites, localized collection and lymphoceles Post-surgery bowel obstruction/ischemia
Therapy and guidance with CT scanning		1. Biopsy and aspiration 2. Pigtail catheterization 3. Nephrostomy catheter placement 4. Radio-frequency ablation 5. Radiotherapy instrument placement

Table 3 (continued)

Region	Area of coverage	Indications
Common acute indication in an oncology hospital		1. Brain metastases/hemorrhage/infarct 2. Pulmonary thrombus 3. Fungal pneumonia 4. Fluid collections and aspirations 5. Bleeder detection for drop in hemoglobin, hematemesis, hemoptysis, malaena, etc. 6. Bowel obstruction, ischemia

MRI is a better modality for evaluating pelvic structures, including the uterus, ovaries, and vagina in females and the prostate and seminal vesicles in males. Local staging of rectal and anal canal cancers is best performed with MRI. Bone and soft tissue tumors are well-characterized on MRI. MRI is a standard modality of choice for characterization of brain tumors, bone tumors, few head and neck tumors, and even for hepatic malignancies

Table 4 Additional applications of CT

Technique	Advantage	Additional scans if required
3D planar reconstruction and volume rendering technique (VRT)	Viewing of the obtained data in all three planes (axial, sagittal, and coronal) with formation of a 3D image of the organ of interest	No
Maximum intensity projection	Good for visualization of the objects having higher density, e.g., vessels in angiography	No
CT volumetry	To obtain an approximate volume of the tumor/fluid collection, which aids in treatment planning	No
CT colonoscopy	• A noninvasive screening tool for colorectal carcinoma • Provides a virtual picture of the entire colon • Detection of more than 6-mm polyps is similar to the results of colonoscopy	An additional prone non-contrast scan with air inflation of the rectum is required
CT bronchoscopy	• Can visualize the tracheobronchial lumen, cartilage rings, and carina, down to the fourth-order bronchial orifices and mimics optical bronchoscopy • This noninvasive modality is highly sensitive to detecting bronchial masses and, along with multiplanar reconstruction, can delineate extraluminal tumor extension (less sensitive in picking mucosal lesions)	No
CT cisternography	Visualization of CSF spaces and cisterns for detection of CSF leaks	An additional prone scan of the peripheral nervous system (PNS) has to be obtained after injection of diluted intravenous (IV) contrast in the subarachnoid space via a lumbar puncture
CT enteroclysis	• Mainly performed to evaluate disease of the small bowel, and it compliments the findings of capsule endoscopy • It is highly sensitive as compared to conventional enteroclysis in detecting inflammatory bowel disease, unexplained gastrointestinal bleeding, and small bowel obstruction along with extraluminal information	No additional scan is required; however, a negative contrast agent that distends the bowel, e.g., mannitol, needs to be administered prior to examination

7 Magnetic Resonance Imaging in Oncology

MRI is one major advance in imaging, which distinguishes itself not only because of lack of ionizing radiation but also because of superior soft tissue resolution and characterization. It helps in characterization of lesions by utilizing the differences in the relaxation times of various tissues, functional aspects such as cellularity, perfusion, angiogenesis, and even metabolite levels in some cases. The widely used applications of MRI have been described in Table 5.

Table 5 Clinical indications and utility of MRI in various regions

Region	Key points	MR pulse sequences/protocol and clinical utility
Brain and spine	MRI helps diagnose a space-occupying lesion and characterizes it as a tumor, depicting its morphology, extent and grade, and prognosis It can help choose an appropriate site for biopsy and assess response, thus differentiating progression from pseudoprogression	Conventional magnetic resonance imaging (MRI) is better than CT in both diagnosis and anatomical details. The sequences used are T1-weighted (T1W), T2-weighted (T2W), fluid-attenuated inversion recovery (FLAIR), and contrast-enhanced sequences. Use of advanced techniques including diffusion-weighted imaging (DWI), magnetic resonance spectroscopy (MRS) perfusion-weighted (PW) imaging, and dynamic contrast enhanced (DCE) MRI provide functional information beyond anatomy and have been commonly used in clinical practice Apparent diffusion coefficient (ADC) maps, fractional anisotropy (FA), cerebral blood flow (CBF), relative cerebral blood volume (rCBV), MR spectroscopy (MRS), and permeability maps may enable identification and differentiation of tumor types, its grade, extent, guide biopsy, and predict early response to treatment
Head and neck	MRI is more accurate in the local staging of cancers of the nasopharynx, oropharynx, salivary glands, nasal cavity, paranasal sinuses, oral tongue, and floor of the mouth Perineural spread, intracranial invasion, dural spread, and retropharyngeal adenopathy are best assessed by MRI. Distinguishing between sinus secretions and tumor, and differentiating between posttreatment changes and residual disease are some of the advantages of MRI	Thinner slices (<3 mm) are important for coronal or sagittal reconstruction because invasion patterns are best appreciated in the nonaxial plane
Orbit	Evaluation of ocular and extraocular tumors, local staging of retinoblastoma (Fig. 4), and optic nerve lesions	T1, T2, post-contrast images with small FOV and planning of sagittal images along the course of the optic nerve for each eye
Chest Mediastinal masses Chest wall masses	MRI enables superior tissue characterization of mediastinal masses with high diagnostic specificity MRI helps differentiate cystic and solid components as well as contents such as fat, hemorrhage, proteins, and fibrosis and also prevents unnecessary diagnostic intervention by characterizing benign findings and improves diagnostic yield by guiding the appropriate site for biopsy Guides the surgeon by depicting the anatomy for planning resection Differentiate malignant from benign osseous tumours and characterise soft tissue tumors MRI is superior to CT in detecting chest wall invasion, particularly in Pancoast tumors	T1W, T2W, Short Tau Inversion Recovery (STIR), DWI, and T2W fat-saturated pulse sequences to differentiate between solid, cystic, proteinaceous, fatty or hemorrhagic lesions and planes with mediastinal structures Pre-gadolinium and post-gadolinium 3D GR DCE sequences for paragangliomas and hemangiomas Ultrafast GRE in-phase (IP) and out-of-phase (OP) chemical shift sequence to see the presence or absence of microscopic or intravoxel fat within a lesion Routine T1W, T2W, STIR, and post-contrast T1W sequences Parallel MRI with high temporal resolution cine imaging, such as steady-state free precession (SSFP) may reveal subtle invasion of mediastinal structures and the chest wall
Body Hepatobiliary and pancreas	MRI is the most superior imaging technique for diagnosis and presurgical planning for hepatobiliary and pancreatic malignancies DCE MRI is the modality of choice for detection and characterization of nodules detected at screening; for staging hepatocellular carcinoma (HCC) as well for surveillance, and follow-up MRI is highly specific for HCC and can avoid an unnecessary biopsy in underlying cirrhosis Newer imaging techniques, including hepatocyte-specific contrast agents and diffusion-weighted imaging, may further improve MRI imaging sensitivity to HCC	SSFSE heavily T2-W sequence-characterises cysts, collections and edema. Hemangiomas too appear bright on this sequence The BSSFP sequence—rapid motion-insensitive bright blood sequence—helps in delineating the vessels, ducts, bowel loops, and fluid collections In-phase and out-of-phase dual GRE (dual fast field echo) for tissue characterization provides sensitivity to microscopic fat (hepatic steatosis, hepatic adenoma, or hepatocellular carcinoma). Susceptibility artifact (detecting iron in abdominal organs, air secondary to disease), and other agents of a low T1 value Dynamic multiphasic 3D fat-suppressed spoiled gradient echo (3D GRE) sequence aids in MRI of the liver, characterizing normal parenchyma from lesions, and delineates vascular structures Hepatocyte-specific contrast agent (HSCAs)-based 3D fat-suppressed spoiled GRE sequences for specific indications Diffusion-weighted imaging (DWI) for solid liver lesions and monitoring response to treatment

Region	Key points	MR pulse sequences/protocol and clinical utility
Prostate	MRI helps in detecting clinically significant cancers, assists in targeting lesions, as cognitive or software fusion, or by MRI-guided biopsies, improving accuracy and selection of higher Gleason-grade lesions It also plays a role in triaging patients for active surveillance	Multiparametric MRI of the prostate offers excellent soft tissue anatomy for different parts of the gland on high-resolution T2W sequences, with superadded functional evaluation from diffusion-weighted imaging (DWI), dynamic post-contrast enhanced imaging (DCE), and optional MR spectroscopy (MRS)
Rectum	Optimal local staging in rectal cancer is performed with MRI by defining the pertinent anatomy of the rectum and showing relation to the surrounding organs and mesorectal fascia. MRI helps decide the need for preoperative chemoradiotherapy, plan surgery, and estimate prognosis	T2-weighted magnetic resonance imaging with small field of view and high resolution is now the first-line imaging tool for evaluation and guiding management for rectal tumors DWI can help in monitoring response to chemoradiation
Bone and soft tissue	MRI is the examination of choice for local staging (intraosseous, extraosseous, neurovascular bundle, and joint involvement), for determining the target and the course of the biopsy tract, and for surgical planning. The entire bone should be scanned including the proximal and distal joints to evaluate for skip metastases MRI, due to its inherent capability to characterize soft tissue, is the preferred modality for soft tissue tumors and tumor-like conditions	STIR is the initial imaging sequence for further planning The T1W sequence is best to show the marrow extent and skip metastases Lobular high-T2-pattern signal intensity is specific for chondroid origin lesions because of the inherent increased water content in the cartilages At least two orthogonal planes, with one being axial plane, should be planned on an MRI T1W and T2W sequences should be obtained because most soft tissue lesions have been described with their spin echo (SE) T1W and T2W signal characteristics DCE sequences by virtue of differential enhancement can differentiate the etiology of benign from that of malignant to some extent but may not always obviate the need for a biopsy
Breast	Adjunct to mammography and USG breast. Some common indications include evaluation of lobular cancers, unknown primary with limited sites of metastases to the axilla and suspected primary in breast, Paget's disease with no abnormality on mammography, patients undergoing partial breast irradiation following a breast conservation surgery, and patients with highly dense breasts for local disease evaluation	Plain T2W/STIR, DWI, and plain T1W (optional) followed by dynamic post-contrast images obtained after a rapid bolus of contrast injection using a gradient echo sequence Subtracted images to be viewed on monitors along with time–intensity curves
Miscellaneous	The pancreatico-biliary drainage system (MRCP) pelvicalyceal system and ureters (MR urography), and other fluid-filled ductal systems are extremely well-visualized without need for a contrast agent	Heavily T2-weighted sequences

3D three-dimensional, *GRE* gradient echo, *DCE* dynamic contrast-enhanced (DCE) imaging, *IP* in-phase, *OP* out-of-phase, *BSSFP* balanced steady-state free precession, *SSFSE* single-shot fast-spin echo, fat-suppressed 3D GRE sequences include LAVA (liver acquisition with volume acceleration), *LAVA-Flex* liver acquisition with volume acceleration-flexible, *THRIVE* T1 high-resolution isotropic volume excitation, *mDIXON* modified Dixon, *VIBE* volumetric interpolated breath-hold examination, *FOV* field of view (FOV)

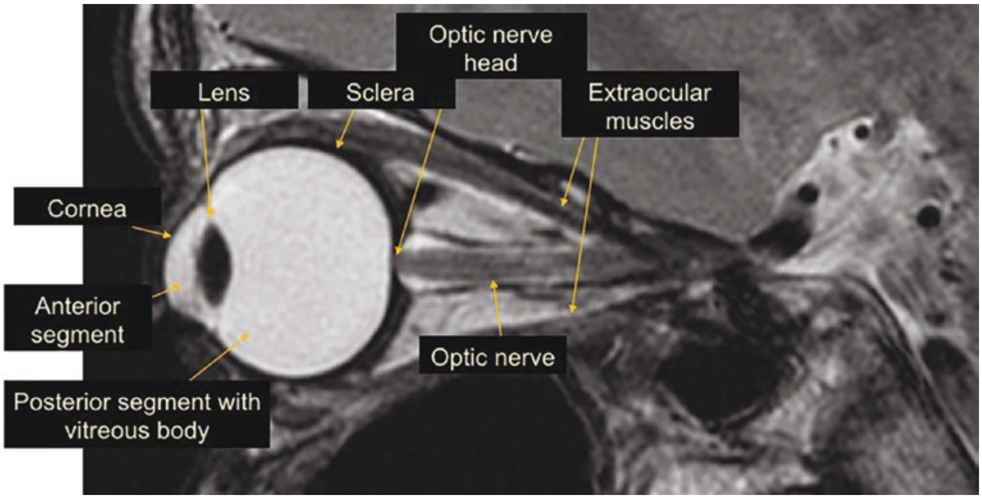

Fig. 4 Sagittal T2W MRI image of the orbit shows the detailed anatomy of the globe and optic nerve

8 Response Evaluation in Oncology

The RECIST (Response Evaluation Criteria in Solid Tumors) criteria, introduced in 2000 and updated (RECIST 1.1) in 2009 are the workhorse for response assessment in most clinical drug trials [8]. These provide guidelines for technical parameters required for imaging cancer patients on trials, how to select and measure the lesions using the single longest diameter, and how to calculate response. RECIST 1.1 defines how to differentiate measurable lesions (broadly, lesions more than 1 cm in size or nodes more than 15 mm in a short-axis diameter on cross-sectional imaging) from nonmeasurable lesions (lesions less than the above size, as also effusion, ascites, peritoneal nodularity, leptomeningeal metastases, bony metastases without a soft tissue component, and other such examples). Up to five lesions on the baseline scan are to be selected as target lesions, with the sum of the longest diameters used for response assessment. Disappearance of all lesions is considered complete response (CR), ≥30% decrease is considered partial response (PR), ≥20% increase is considered progressive disease (PD), whereas anything in between is considered stable disease (SD). Appearance of a new measurable lesion or unequivocal progression of nonmeasurable disease is also considered PD.

The size-based RECIST criteria are, however, found lacking in assessing response to newer treatments and also for assessing specific cancers such as gliomas, and multiple alternate response criteria have also emerged for specific usage. These include the Choi criteria for use in patients on targeted therapy (classically gastrointestinal stromal tumor (GIST) patients on imatinib) [9], iRECIST [10] criteria for patients on immunotherapy, RANO (Response Evaluation in Neuro-oncology) criteria for gliomas, Deauville criteria for lymphomas, mRECIST criteria for hepatocellular carcinomas, and PERCIST (Positron Emission Tomography Response Criteria in Solid Tumors) criteria for PET/CT assessment of response.

9 Molecular and Functional Imaging in Oncology

MRI technology has not only helped in anatomical soft tissue characterization and delineation of abnormalities but has also taken imaging to the functional and cellular levels using various techniques such as perfusion, vascular permeability, tissue oxygenation [blood oxygenation-level dependent (BOLD) technique] [11] and cellular status, density, and microstructural organization (diffusion technique) [12, 13].

Molecular diffusion is a reflection of the free Brownian motion in the cellular microenvironment, based on media viscosity, temperature, molecular mass, and the value measured as apparent diffusion coefficient (ADC) [14]. Tumor ADC maps help in differentiating enhancing lesions, peritumoral edema, and cystic/necrotic changes from the surrounding structures. It aids in characterization, assessment of the grade of tumor, tumor cellularity, and response to chemotherapy.

Use of imaging biomarkers for assessment of tumor angiogenesis is on the rise for understanding the effect and activity of the pharmacodynamics of the drugs used. Dynamic contrast-enhanced MRI assesses tumor pathophysiology, response assessment to radiotherapy, and antiangiogenic agents. Intravenous contrast gadolinium, once injected, with subsequent acquisition of serial dynamic images, based on a compartment model (accounting for tissue perfusion and vascular space), generates a set of parameters such as blood flow, blood volume, vessel permeability, and extracellular extravascular space [15]. Perfusion kinetics are often used for determining residual/recurrence disease and response assessment in addition to morphological imaging.

MR spectroscopy (MRS) detects tissue metabolites containing protons [16], phosphorus, or enriched carbon [17]. Proton MRS has a promising role in guiding biopsies in organs such as the brain, breasts, and prostate, based on the choline:creatinine ratios. Decrease in choline levels may also be seen as a response to therapy.

Molecular functional imaging (MFI) techniques are used in addition to anatomical delineation, forming an essential part of cancer management, providing metabolic and functional information. These have been briefly summarized in Table 6.

Table 6 Molecular imaging techniques: principle and applications

Imaging technique	Principle	Applications
Contrast-enhanced ultrasound	Gas-filled microbubbles are used as contrast media. They are intravenously introduced into the systemic circulation, enabling the visualization of tissue vascularity and perfusion on real-time ultrasound	1. Measuring blood volume and perfusion 2. Lesion characterization—benign vs. malignant 3. Gene delivery and drug delivery—future applications
Ultrasound elastography	Cancer tissues, by virtue of their cellularity and desmoplasia, are more stiffer than are normal tissues and most benign lesions. A measure of elasticity, perceived by the extent of deformation of ultrasound waves, helps estimate the likelihood of a malignancy	1. Differentiating benign from malignant lesions, particularly in the breast, liver, prostate, and thyroid
Computed tomography (CT) perfusion imaging	It provides information about hemodynamics at the capillary level of various tissues. Monitoring the first pass of an iodinated contrast agent bolus through the organ of interest can determine perfusion	1. Differentiating benign from malignant lesions on the basis of the components of angiogenesis 2. Help in guiding biopsy by highlighting the area with higher angiogenesis, thus increasing the likelihood of a core with a better diagnostic yield 3. It can help monitor the response to therapy
Computed tomography (CT) texture analysis	The texture concept in a CT image is the distribution of gray-level values (or heterogeneity) in the region of interest in an image. CT texture analysis objectively measures the amount of heterogeneity in a given tissue, with the data represented as a statistical chart	1. Texture analysis of cervical cancer, colon cancer, and lung cancer helps differentiating from benign conditions. It also helps in response assessment 2. Utility as an imaging-based biomarker for gene expression
Positron emission tomography (PET)	It is a functional imaging modality, which detects 1. Blood flow 2. Glucose metabolism 3. Receptor density A radioactive tracer is intravenously injected. The tracer is taken up by the tissue of interest. The tracer decays and emits a positron, which itself, on further decay, emits a pair of gamma rays. These gamma rays are detected by a scintillator, with post-processing software generating a medical image	1. Workhorse for functional oncological imaging in detecting primary disease, recurrent disease, nodal involvement, and metastatic disease and in assessing response to therapy. Used as a cancer-staging modality 2. It is also used prior to stereotactic surgery to guide the resection of brain tumors
Single photon emission computed tomography (SPECT)	In SPECT, a gamma ray-emitting radioactive substance (most commonly used: technetium) is intravenously injected and imaging is performed using a gamma camera. Radioactive substance concentration in the tissue of interest and three-dimensional information regarding the tissue of interest are detected by the camera	1. Bone scan for metastatic bone disease, metabolic disorders, etc. 2. Sestamibi scan for parathyroid disorders 3. Metaiodobenzylguanidine (MIBG) imaging and therapy for neuroblastoma 4. Peptide receptor radionuclide therapy (PRRT) for neuroendocrine tumors
Magnetic resonance spectroscopy (MRS)	Magnetic resonance spectroscopy (MRS) quantifies levels of metabolites in body tissues after fat and water suppression. The MR signal amplifies the microquantities of the titers of these metabolites, thus producing a spectrum of resonances. Fluctuations in these metabolites reflect a pathology. For example, choline is a primary phospholipid of the cell membrane, and thereby, an increase in its concentration reflects greater cell division, as seen in malignancies. In lesions of a neuroparenchymal origin, this is accompanied by reduced *N*-acetyl aspartate due to neuronal loss. Increased lactate levels reflect the anaerobic processes in malignancies or infections. Citrate is a normal component of prostate cells and, similarly, its levels are decreased in prostate cancer	1. Characterization of brain tumors, benign pathologies, infective lesions, etc. It may provide an insight into differentiating from tumor mimics such as tuberculosis and fungal etiology, in assessment of tumor progression from pseudoprogression and radiation necrosis 2. It is also used for detection of carcinoma of the prostate 3. Other applications include breast cancer and cervix cancer
MRI diffusion-weighted imaging (DWI)	The movement of free water molecules in extracellular space is restricted in an environment with many more cells in number and larger sizes of cells, both associated with cancer cells, and few pathological conditions like abscesses. This, in turn, can restrict the movement of water molecules in biological tissues. Changes in tumor cellularity and cell membrane integrity can be estimated qualitatively and quantitatively	1. Diagnosis of acute stroke 2. Characterizing brain tumors and certain infective lesions 3. Assessing response to treatment of tumors in various organs throughout the body

(continued)

Table 6 (continued)

Imaging technique	Principle	Applications
Magnetic resonance perfusion imaging	Perfusion-weighted imaging reflects the vascular perfusion of organs and tissues. It detects angiogenesis as well as predicts and quantifies the response to antiangiogenic therapy. Angiogenic blood vessels are more permeable than are normal vessels, thereby allowing contrast passage into the tissues. First, T1-weighted dynamic contrast-enhanced imaging determines leakage from permeable blood vessels as a surrogate marker for angiogenesis. Second, the T2*-weighted sequence for dynamic susceptibility contrast imaging measures the relative blood volume (rBV) corresponding to capillary density, reflecting the tumor grade	1. Primarily, perfusion imaging evaluates ischemic conditions such as acute cerebral infarction where identifying the ischemic penumbra can help in patient management and in conditions like Moyamoya disease 2. Grading of tumors such as diffuse astrocytomas often simulate higher values of perfusion 3. Assessment of response, determining residual disease, and recurrence
Functional MRI (fMRI): BOLD and hypoxia imaging	Functional MRI (fMRI) measures neuronal activity-induced signal changes, where increased activity results in increased vascularity, greater influx of oxyhemoglobin (more than that required for metabolism), and relative decrease in deoxyhemoglobin. The latter is paramagnetic, and, hence, its decreased level increases the magnetic signal intensity. This is called the BOLD (blood oxygen-level dependent) effect The presence of hypoxia contributes to poor prognosis, with important consequences for diagnosis and treatment. For example, the oxygenation status in cervical cancer is independent of size, stage, pathological type, or grade of the tumor	1. Planning neurosurgery to assess which regions can be excised without compromising the patient's neuronal status 2. Mapping the location of tumors, extent of stroke and head injuries, and conditions like Alzheimer's, where the epicenter of the pathology and its adjoining effect can be neurologically mapped for estimated deficit 3. In psychiatry for behavioral therapy and assessing response to it 4. Hypoxia imaging in tumors
Ultrasmall particle iron oxide (USPIO) MRI	USPIO developed for MRI of the reticulo-endothelial system (lymph nodes and liver), causes signal drop on T2* imaging. Accumulation of iron oxide nanoparticles in macrophages is the basis for nodal imaging with dextran-coated USPIO agents	It is used to distinguish metastatic lymph nodes that may not be morphologically abnormal in size or to differentiate enlarged metastatic nodes from enlarged reactive/benign hyperplastic nodes
MR elastography	Magnetic resonance elastography (MRE), a novel imaging method synchronizes motion-sensitive phase-contrast MR sequences to application of acoustic waves. Mechanical waves are propagated using MRI for quantitative stiffness information, especially in anatomically inaccessible sites such as the brain	

10 Conclusions

To summarize, imaging plays a vital and specific role in delivering optimal care in oncology. A sound knowledge of the pros and cons of different imaging techniques can help in choosing the optimal modality for a given patient.

1 History

Nuclear medicine involves the administration of a fixed amount of radiolabeled pharmaceuticals to the patient with the intention of providing therapy and diagnosis. Nuclear medicine can be considered to have originated with the discovery of radioactivity itself as a result of the works of Dr. Henry Becquerel and Marie Currie [1]. It really took off with the invention of the cyclotron by Ernest Orlando Lawrence in 1930 [2]. However, we had to wait until the 1950s to acquire the technologies that could obtain images of radioactivity distribution in the body. The first of such technologies was invented by Benedict Cassen with the development of a rectilinear scanner in 1951 [3]. Then came the Anger camera, developed by Haul Anger in 1958, who is considered the forefather of all other gamma cameras to follow [4]. In 1951, Wrenn and coworkers discovered the favorable imaging characteristics of positron-emitting radioisotopes [5].

Iodine-131 (I-131) had been the foremost radioisotope used in medicine for a long time, which changed in 1964 when Paul Harper started using technetium-99m (Tc99m) for imaging [6]. Tc99m proved to be an excellent agent for imaging. Gamma rays emitted by Tc99m have favorable imaging properties, and, being chemically versatile, Tc can label a huge number of pharmaceuticals.

Initial gamma camera imaging was planar, which did not offer good resolution and anatomical localization; however, technologies for tomographic reconstruction have significantly changed this. This led to the development of positron emission tomography (PET) imaging by Phelps et al. [7] and single photon emission computed tomography (SPECT) by Kuhl et al. in 1970s [8]. PET imaging has become ubiquitous in medical practice; this is primarily due to the advent of the metabolic tracer [^{18}F]fluorodeoxyglucose (^{18}F-FDG). Finally, the advent of fusion imaging modalities such as PET/computed tomography (CT) and SPECT/CT has revolutionized diagnostic imaging, especially in oncology.

Use of radioisotopes in therapy is even older than imaging. In the early 1940s, iodine-131 (I-131) was successfully used to treat metastatic follicular thyroid cancer. Phosphorus-32 (P-32) was the first radionuclide used for cancer treatment of leukemia and polycythemia vera. From the era of P-32 and I-131, we have now come to the era of lutetium-177 (Lu-177), a versatile tracer that can be tagged with a plethora of pharmaceuticals and can be used for therapy.

2 Radiopharmaceuticals

A radiopharmaceutical is a chemical compound that has been tagged with a suitable radioisotope. These chemicals, after administration, get localized to specific organs or disease sites in the body depending on their specific pharmacodynamic and pharmacokinetic properties and emit radiations of various types. Thus, they can portray physiology, biochemistry, or pathology within the body. Depending on the emitted radiation, a particular radiopharmaceutical can be used for either diagnosis or therapy. The radiopharmaceuticals that emit non-particulate electromagnetic radiations like gamma (γ) rays can be used for diagnostic imaging, whereas the ones emitting particulate radiation such as alpha (α) and beta (β) are used for therapeutic purposes. Each radiopharmaceutical will have a specific decay characteristic and half-life of the tagged radioisotope. Radioisotopes for therapy and diagnosis are produced by three main methods: nuclear reactor, cyclotron, or on-site generator systems. Generators such as molybdenum–technetium (Mo-Tc) generators and germanium–gallium (Ge-Ga) generators are enabling nuclear medicine departments to produce important radiopharmaceuticals on-site. Few of the most commonly used radiopharmaceuticals with their clinical uses are summarized in Tables 1, 2, and 3.

Table 1 Gamma camera radiopharmaceuticals

Radiopharmaceutical	Physiological principle	Clinical use
Tc^{99m} MDP	Bone turnover	Skeletal metastasis, primary bone tumor, arthritis
Tc^{99m} DTPA	Glomerular filtration	Renal function (GFR) and drainage
Tc^{99m} EC	Tubular secretion	Renal function and drainage
Tc^{99m} DMSA	Cortical fixation	Renal scars
Tc^{99m} sestamibi	Myocardial perfusion	Coronary artery disease—reversible ischemia
Tl^{201} chloride	Myocardial perfusion	Coronary artery disease—reversible ischemia and myocardial viability
Tc^{99m} ECD	Brain perfusion	Epilepsy, dementia
Tc^{99m} MAA	Lung perfusion	Pulmonary embolism
Ga^{67} citrate	Iron-binding protein	Tumor imaging, infection imaging
NaI^{123}	Sodium iodine symporter (NIS)	Thyroid imaging—benign and malignant diseases
I^{123} MIBG	Presynaptic uptake	Neural crest tumors
In^{111}-labeled leukocytes	Chemotaxis	Infection imaging

Table 2 PET radiopharmaceuticals

Radiopharmaceutical	Physiological principle	Clinical use
F^{18} FDG	Glucose metabolism	Tumor imaging, infection, and inflammation imaging
F^{18} NaF	Bone turnover	Bone metastasis, primary bone tumor
Ga^{68} PSMA	Receptor imaging	Prostate carcinoma
Ga^{68} DOTA-NOC	Receptor imaging	Neuroendocrine tumor
Rb^{82} chloride	Myocardial perfusion	Coronary artery disease—quantification of myocardial blood flow

Table 3 Therapeutic radiopharmaceuticals

Radiopharmaceutical	Physiological principle	Clinical use
NaI^{131}	Sodium iodine symporter (NIS)	Carcinoma thyroid, Grave's disease, toxic multinodular goiter
Sm^{153} EDTMP	Bone turnover	Palliation of metastatic bone tumor
I^{131} MIBG	Presynaptic uptake	Neuroectodermal tumors
Lu^{177} DOTATATE	SSTR receptor (PRRT)	Neuroendocrine tumors
Y^{90} spheres	Transarterial radioembolization (TARE)	HCC, metastatic liver cancer
Re^{186} colloid	Intrasynovial injection (radiosynovectomy)	Rheumatoid arthritis

3 Positron Emission Tomography (PET)

Positron emission tomography using positron-emitting radiopharmaceuticals has revolutionized diagnostic imaging in clinical oncology. This special characteristic of positron emission is utilized in a special capacity for imaging. A positron, after being emitted by a radioactive nucleus, interacts with a local electron to produce a pair of annihilation photons, which, when emitted in an opposite direction on being detected by a circular array of scintillation detectors create a coincidence event [9]. This is known as annihilation coincidence detection (ACD). This method is successfully utilized to detect positron distribution in an injected patient. Along with ACD, some PET cameras are now using a newer technology, eponymously named time of flight (TOF). This technology has improved the resolution of PET systems. A PET system provides not only better resolution but also better quantification as compared to its gamma camera counterpart, SPECT [10].

Of all the PET tracers, ^{18}F-FDG is still the most important and commonly used. Along with its use in oncology, ^{18}F-FDG is being increasingly being used in cardiology, neurology, infections, and rheumatological indications. As a glucose surrogate, FDG targets the glycolytic pathway for intracellular sequestration and shows increased uptake by malignant cells and active inflammatory cells. This is the principle of ^{18}F-FDG/PET imaging [11]. Other than ^{18}F-FDG, other commonly used PET tracers are 18F-sodium fluoride (F18 NaF) for evaluation of bone metastasis, N13 ammonia and Rb82 for myocardial blood flow evaluation, and Ga-68-labeled receptor imaging in carcinoma prostate and neuroendocrine tumors (NETs) [12].

4 Radiommunodiagnostics

Radioimmunodiagnostics is the use of radiolabeled monoclonal antibodies for diagnostic imaging. It is used in diagnosis, assessing treatment response, and to select suitable patients for immunotherapy and targeted drug delivery. It depicts the heterogeneity of the primary tumor and metastatic sites and predicts the response to therapy. Common targets are CD20, CD44, epidermal growth factor receptor (EGFR), vascular epidermal growth factor receptor (VEGFR), human epidermal growth factor receptor 2/neu (HER2/neu), and prostate-specific membrane antigen (PSMA) [13]. Commonly used radioisotopes are zirconium-89 (Zr-89), copper-64 (Cu-64), and iodine-124 (I-124). Previously, the whole of monoclonal antibodies were used for imaging purposes; however, now there is a move toward the use of antibody fragments with smaller molecular size such as affibodies, diabodies, and nanobodies [14]. These newer agents have faster blood pool clearance and help perform early imaging. Some of the agents with active research interest are listed in Table 4.

Table 4 Radioimmunodiagnostic agents

Radiopharmaceuticals	Target	Tumor
Zr89 bevacizumab	VEGF	Breast cancer, multiple myeloma
Zr89 trastuzumab Cu64 trastuzumab	HER2/neu	Breast cancer
Zr89 cetuximab	EGFR	Colorectal cancer
Cu64 rituximab	CD20	B cell lymphoma
Zr89 PSMA	7E11	Prostate cancer
Zr89 cG250 I124 cG250	CA IX	Renal cell carcinoma

5 Hybrid Imaging

The fusion imaging concept came to the fore in order to combine the functional and anatomical modalities together to get structural and pathophysiological information in the same imaging. Various anatomical imaging modalities like computed tomography (CT) and magnetic resonance imaging (MRI) were considered for fusion with existing functional imaging modalities like SPECT and positron emission tomography (PET). The dual imaging modalities that have been prominently used till date are SPECT/CT, PET/CT, and PET/MRI.

Three-dimensional (3D) reconstructive nuclear medicine imaging techniques have relatively poor resolution. The also provide no anatomical information. On top of that, there can be significant loss of counts during the reconstruction process itself. Thus, image fusion became a necessity to ensure visual quality and quantitative accuracy. Co-registration of anatomical and physiological information has revolutionized molecular imaging by helping differentiate abnormal uptake from physiological uptake. Quantification of tissue uptake and organ functions could also be further improved by correcting the emission data for errors due to photon attenuation, partial volume effect, scatter radiation, etc., using the attenuation correction information obtained from CT [15].

Most SPECT scanners, nowadays, have a dual-headed camera system with an integrated CT scanner. SPECT and CT scans are acquired successively and fused together to create a hybrid image. This hybrid image not only helps localize the uptake to the proper anatomical sites but the CT scan thus obtained can also be used for attenuation and scatter correction of gamma rays. Along with routine diagnostic imaging, new indications of hybrid SPECT scanners are emerging in the field of dosimetry and radiopharmaceutical research. SPECT/CT technology has improved the sensitivity and specificity of gamma camera imaging and has thus reduced the number of indeterminate scans [16].

The first hybrid PET/CT scanner was designed in the late 1990s [17]. Since then, there has been a rapid surge in the commercial implementation of hybrid PET/CT scanners, partly fueled by the increasing interest in diagnostic ^{18}F-FDG whole-body cancer studies. The cross-sectional CT component helps identify the precise anatomical location of FDG-avid areas. Furthermore, the CT attenuation map generated can be used to correct the PET attenuation caused by different tissues. In many cancers, such as lymphomas and malignant melanomas, carcinoma lung PET/CT has become indispensable to staging and response assessment and its use has been adopted into clinical guidelines. There are many clinical situations where MRI is the investigation of choice and provides better anatomical information than does CT scanning. PET can complement the MRI findings with more functional information. However, integrating PET or SPECT is challenging. With recent technological advancements, commercial hybrid PET/MRI systems have come into the market [18]. However, cost is an important factor inhibiting their widespread clinical adoption.

6 Indications of F18-Labeled Radiopharmaceuticals in Clinical Oncology

6.1 ^{18}F-FDG

^{18}F-FDG is the principle oncological tracer. F18 has a half-life of 110 min. It is produced in the cyclotron by ^{18}O (p,n) 18F nuclear reaction using $H_2{}^{18}O$ as the target. ^{18}F-FDG is an analogue of glucose and gets metabolically trapped as FDG-6-phosphate inside tumor cells. Tumor cells alter their metabolism to selectively increase energy generation via the glycolytic pathway [19]. This phenomenon is known as the Warburg effect. The clinical uses of ^{18}F-FDG PET/CT have increased immensely in the past two decades [20, 21]. Indications of ^{18}F-FDG PET/CT in oncology can be summarized in the following points:

1. Initial staging in patients with a known malignancy
2. Monitoring response to therapy excluding residual disease
3. Restaging in the setting of relapse
4. Identification of the primary tumor in the presence of a metastatic lesion
5. Localizing occult disease in patients with an elevated tumor marker
6. Guiding special clinical strategies such as radiotherapy planning and directed biopsy
7. Evaluating an indeterminate lesion detected by anatomical imaging to differentiate benign from malignant
8. After treatment completion as a follow-up investigation

6.1.1 The Role of FDG PET/CT in Specific Tumors

Lymphomas

^{18}F-FDG PET/CT has become indispensable to staging, assessing response to treatment, and restaging of FDG-avid lymphomas [22]. It is performed at the initial evaluation stages in about 30% cases [23]. It has excellent sensitivity in picking up both the nodal and extranodal disease sites (Fig. 1). FDG scores over marrow biopsy in detecting lymphomatous marrow lesions in Hodgkin's lymphoma and is considered equal to marrow biopsy in non-Hodgkin's lymphoma [24]. The Deauville five-point scale is used for evaluating the response at interim or at the end of the treatment. Interim ^{18}F-FDG PET/CT performed for response assessment has emerged as an important tool for prognosis. New evidence has emerged in Hodgkin's lymphoma in favor of using interim PET/CT for response-adapted treatment [25].

Lung Cancers

^{18}F-FDG PET/CT with contrast is now widely used to stage the primary lesion and regional lymph nodes. In addition, it is an excellent tool to detect distant metastases, except brain metastases (Fig. 2). ^{18}F-FDG PET/CT is recommended by the National Comprehensive Cancer Network (NCCN) as a standard diagnostic procedure in the pretreatment evaluation of all operable lung cancers [26]. It is a useful adjunct in the characterization of indeterminate solitary pulmonary nodules and pretreatment staging of lung cancer with additional information about the primary tumor, mediastinal nodal status, and remote metastases when compared to a conventional modality like CT [27]. ^{18}F-FDG PET/CT and MRI brain have become the standard staging workups worldwide [28]. They also play a role in guiding the proper biopsy site, radiotherapy planning, response assessment, and restaging. The potential of ^{18}F-FDG PET/CT to provide information about

the metabolism of a tumor has been used to prognosticate patients.

Esophageal Carcinoma

For primary tumor (T) staging, PET/CT is inferior to endoscopic ultrasound to accurately measure the depth of invasion. ^{18}F-FDG PET/CT scores highly in detecting nodal and distant metastases and outperforms conventional imaging. PET/CT has extremely high sensitivity and specificity of 96% and 95%, respectively, for detecting nodal disease [29]. PET/CT scores over other modalities in detecting distant metastasis and prevents unnecessary surgical explorations by detection of metastatic disease. In approximately 40% of patients, PET/CT changes clinical management [30, 31]. It also helps in assessing response to neoadjuvant chemotherapy and concurrent chemoradiation by excluding residual disease.

Bone and Soft Tissue Tumors

^{18}F-FDG PET/CT has an important role in the staging of high-grade sarcomas. In Ewing sarcoma, PET/CT has outperformed conventional modalities in staging and detecting early recurrence [32]. It has also shown usefulness in the detection of the primary tumor and metastases in other sarcomas like osteosarcoma and rhabdomyosarcoma [33]. In addition, PET/CT is now used for assessing response to neoadjuvant chemotherapy in sarcomas. PET/CT can also demonstrate areas of sarcomatous changes in benign chondroid tumors by identifying the hypermetabolic focus [34].

Head and Neck Malignancies

PET/CT has high diagnostic accuracy in detecting nodal and distant metastases in head and neck primary tumors as well as sites of the second primary. Early detection of distant metastases can change the treatment plan accordingly. PET/CT has a high negative predictive value of almost 100% for distant metastases [35]. It is used for response assessment after chemoradiotherapy and is recommended after 8–12 of treatment completion to avoid false-positive inflammatory FDG uptake. It has a high negative predictive value in posttreatment evaluation to rule out residual or recurrent disease [36].

Breast Carcinomas

PET/CT scores highly in ruling out distant metastasis in cases of locally advanced breast carcinoma. It is also used in evaluating indeterminate lesions detected on conventional staging modalities like CT or bone scanning. FDG PET/CT has a questionable role in the detection of axillary nodes. However, its sensitivity for detecting internal mammary nodes is high. It can also predict the outcome after neoadjuvant chemotherapy [37, 38].

Melanomas

FDG PET/CT is the best modality to evaluate nodal and distant metastases in advanced cutaneous melanomas [39]. It is also widely used for detecting metastases from mucocutaneous melanomas in the anorectum and head and neck region.

Cancer of Unknown Primary

Early detection of cancer of unknown primary is important for avoiding unnecessary investigations and starting tumor-specific therapy. FDG PET/CT plays a role in detecting cancer of unknown primary in about 30–50% of cases [40].

Colorectal Carcinomas

PET/CT is often used as a second-line imaging tool in the initial staging of colorectal malignancies. It helps in better characterization of indeterminate liver lesions and is used in evaluating extrahepatic disease before the surgical resection or ablation of liver metastases [41]. PET/CT has an important role in the evaluation of recurrent colorectal carcinomas presenting with rising carcinoembryonic antigen (CEA) levels with a sensitivity of more than 94% for detecting recurrence [42].

Apart from this, PET/CT has an obvious role in tumors like gastrointestinal stromal tumors (GISTs), gall bladder and biliary tract malignancies, poorly differentiated carcinomas of the thyroid, malignant mesotheliomas, cervical cancers, urothelial carcinomas, germ cell tumors of the testis, poorly differentiated neuroendocrine tumors, etc. Evidence of FDG PET/CT in many indications is still emerging and is bound to become more defined with continuing research.

6.2 F18 NaF

^{18}F-sodium fluoride is a PET-based bone scan tracer. F18 fluoride localizes to areas of active bone turnover by chemical adsorption [43]. It clears from the blood faster than the other popular bone-seeking radiopharmaceutical, methylene diphosphonate (MDP). The uptake of F18 NaF is dependent on blood flow and bone remodeling. PET technology also offers better resolution than does planar imaging, and, when performed as a part of hybrid PET/CT imaging, CT allows better morphological characterization of the lesion. The most important indication of F18 NaF in oncology is to detect and characterize metastatic bone lesions (Fig. 3). Other indications where F18 NaF is useful in oncology are to determine the viability of bone graft and also the areas of increased osteoblastic activity as a prelude to bone pain palliation therapy with radiopharmaceuticals [44].

6.3 ^{18}F FLT (3′-Deoxy-3′-^{18}F Fluorothymidine)

This is a surrogate of nitrogen base in DNA strands. It enters a cell by active transport and is trapped after undergoing phosphorylation by thymidine kinase 1. Unlike thymidine, F18 fluorothymidine cannot be incorporated into DNA strands and gets trapped inside the cell. F18 FLT uptake is a marker of thymidine kinase 1 expression and thus cellular proliferation [45]. Various studies have shown that there is a strong correlation between the proliferation marker “Ki-67” detected in histopathology and F18 FLT uptake [46]. Studies have shown that FLT has an important role in grading gliomas and detecting recurrence. One disadvantage of F18 FLT is that it does not cross the blood–brain barrier and so it will not be concentrated by low-grade gliomas where the blood–brain barrier stays intact [47]. It has shown promise in guiding and planning of radiotherapy and assessing treatment response.

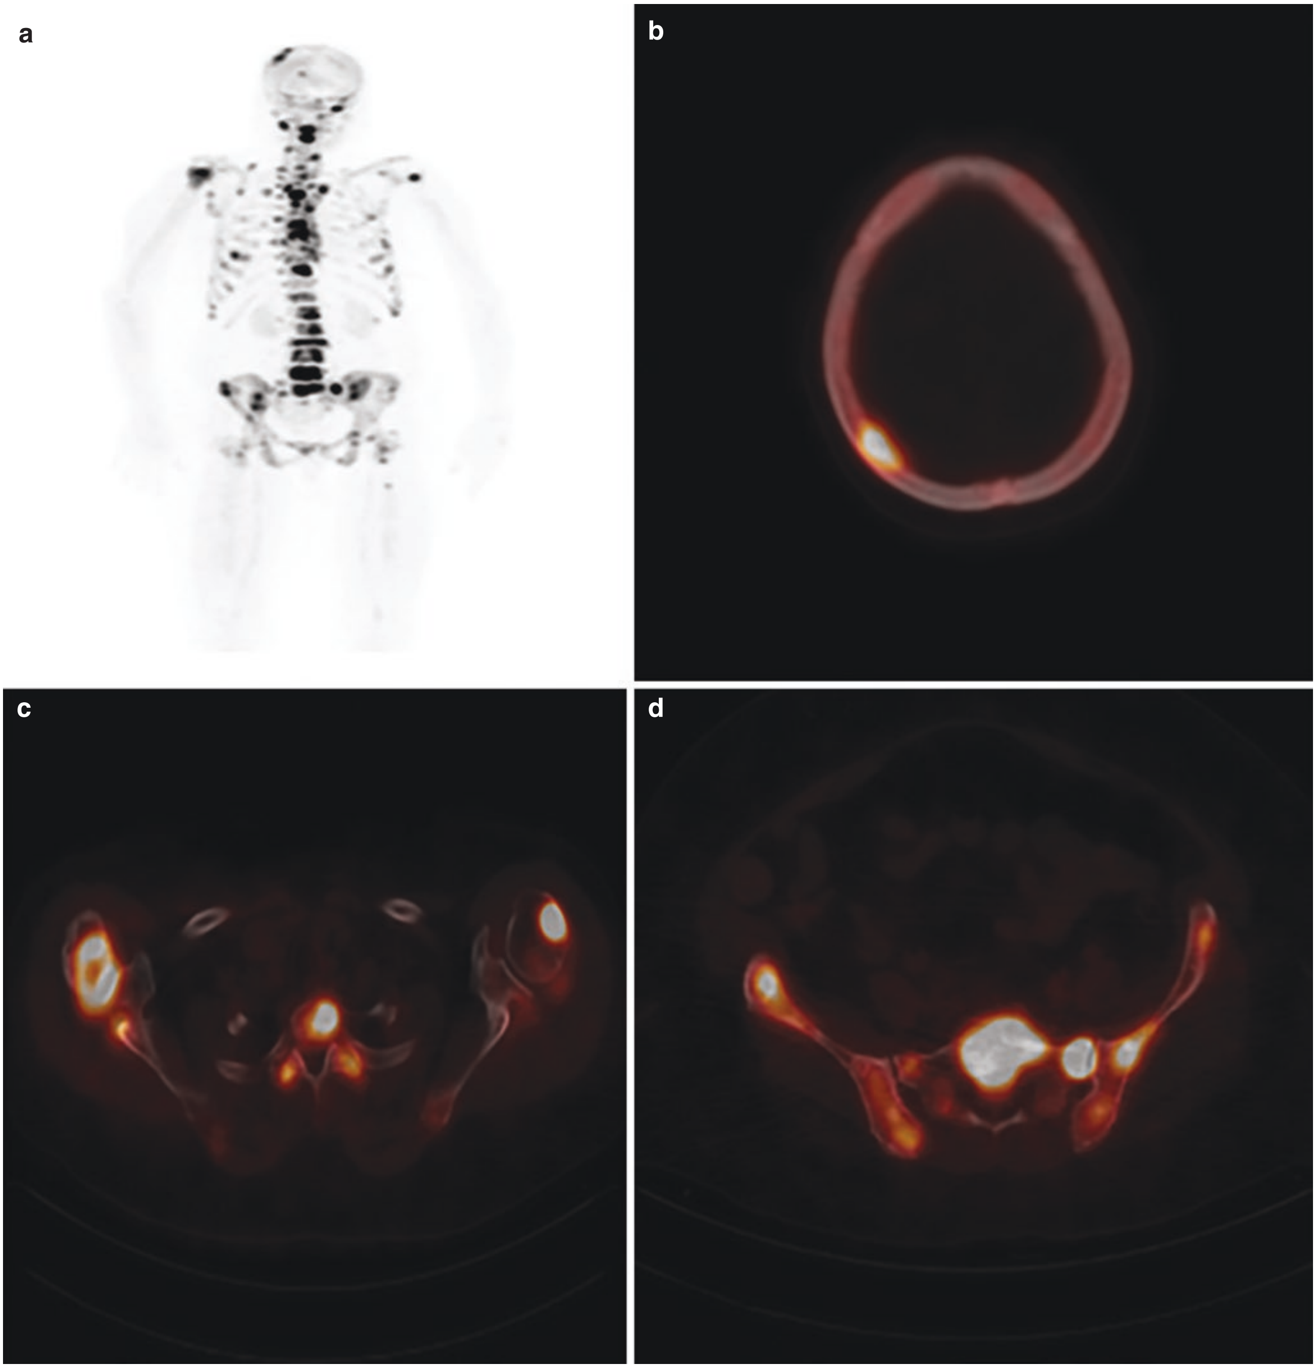

Fig. 3 F18 NaF PET/CT images of a 44-year-old woman with locally advanced carcinoma of the left breast. Maximum intensity projection (MIP) and fused transaxial images are shown. MIP (**a**) showing extensive skeletal metastases involving the axial and appendicular skeletal system. Transaxial images showing metastases in (**b**) the skull, (**c**) bilateral humeri, dorsal vertebra, and (**d**) sacrum and bilateral iliac bone

6.4 F18 FMISO (F18 Fluoromisonidazole)

This is an imaging agent for hypoxia. This particular molecule has a $–NO_2$ functional group. In the absence of oxygen, this group is reduced by accepting an electron in the anionic form of $R\text{-}NO_2$. If reduced, then this moiety becomes an alkylating amine ($R\text{-}NH_2$) compound and is retained in the cell, thus getting trapped effectively [48]. Uptake of F18 FMISO in a tumor depends on the degree of hypoxia and the biology of the tumor. Hypoxia makes cancer cells more resistant to radiation and a number of chemotherapeutic agents. The level of hypoxia in a tumor is also an important prognostic marker [49]. Locating hypoxic regions in a solid tumor will thus help in proper therapy planning. F18 FMISO

PET/CT imaging has been used for localizing hypoxic sites and then using these images for radiation treatment planning. Several studies have demonstrated that hypoxia and FMISO uptake in variety of solid tumors like glioblastoma multiforme, lung cancer, cervical cancer, head and neck cancer, and breast cancer correlates with tumor prognosis [50].

6.5 ^{18}F FET (^{18}F-Fluoro-ethyl-tyrosine)

This is an amino acid tracer that can enter the brain parenchyma through an intact blood–brain barrier using the L-type amino acid transporter 1 (LAT1). This unique mechanism of localization has made this a highly lucrative tracer for imaging gliomas [51]. Unlike FLT, it shows localization in low-grade gliomas as well. It can also help differentiate between low-grade and high-grade gliomas. In high-grade gliomas, there is rapid uptake and washout, and, in low-grade gliomas, there is gradual accumulation of the tracer. These uptake patterns can be easily discerned by performing a dynamic study and plotting a time–activity curve or by carrying out multiple static images at different time points. Apart from grading gliomas, F18 FET also helps in diagnosing recurrence, evaluating treatment response, and planning radiotherapy. Studies have been conducted to evaluate the role of F18 FET in prostate cancer, meningioma, and pediatric lymphomas [52].

7 Radioguided Surgery and Radioguided Biopsy

The sentinel lymph node (SLN) biopsy is the most popular radioguided technique. It increases the identification rate of occult lymphatic metastases and also obviates the need of blind lymph node biopsies. Lymphoscintigraphy prior to surgery helps map out the drainage patterns to guide the surgeon toward the sentinels. An intratumoral or peritumoral injection of technetium-99m sulfur colloid is performed, guided by ultrasound or computed tomography, up to 24–36 h prior to surgery [53]. Intraoperative “hot” node detection is then carried out with the help of a gamma probe. Due to better special resolution and having a cross-sectional imaging component, SPECT/CT improves SLN detection. This technique of radioguided biopsy is being used in head and neck cancers, breast cancer, penile carcinoma, malignant cutaneous melanoma, and carcinoma of the cervix [54]. Another radioguided procedure in surgical oncology is resection of the parathyroid adenoma. Parathyroid scintigraphy can be used not only to localize parathyroid adenoma but also to help determine whether the surgery is successful [55].

Radioguided biopsy has been gaining much popularity in recent years as FDG PET/CT modality has become more ubiquitous. FDG PET helps identify the most metabolically active lesions and also helps guide the biopsy site by decreasing nondiagnostic sampling. A PET-guided biopsy can be performed in two different ways: the first one is to obtain a PET scan separately and then to fuse it with the CT image/MRI image of the guided biopsy procedure. Alternatively, a real-time PET/CT scan can be performed and a biopsy can be obtained simultaneously, thus saving time. In real-time imaging, single-bed PET/CT is performed to confirm the biopsy site and the biopsy is collected. Most commonly, it is used for diagnosis of lymphomas, carcinomas of the lungs, bone, liver, and soft tissue lesions [56, 57]. Increased cost and increased radiation exposure preclude the widespread availability of this procedure.

7.1 PET/MRI Hybrid Imaging

Both positron emission imaging and magnetic resonance imaging are well-established diagnostic tools that have been in use for more than 30 years. With the advent of PET/CT hybrid imaging, a new era of diagnostic imaging has begun. This increasing focus on the fusion of anatomical and functional data has led to rapid growth in PET/CT technology and application. However, there are many clinical conditions where CT does not provide adequate morphological information but MRI does. This has led to the development of hybrid PET/MRI systems [58]. The usual workflow of PET/MRI is an integrated system in which PET detector rings are placed inside the MRI gantry. The integrated design allows simultaneous PET and MRI with reduced scanning time and improved registration in the fusion images [59].

In spite of the theoretical promise, there are many unique challenges specific to PET/MRI systems that preclude their widespread use. Most of these are technical issues inherent to the PET/MRI system [60]. The PET components of the system should be devoid of any ferromagnetic substance; this poses a great challenge to designing systems. However, the most pressing challenge comes in the form of attenuation correction [61]. Without a transmission CT scan to generate a linear attenuation coefficient map for attenuation correction, other techniques have to be employed for that. Many different techniques have been used, such as using special MRI sequences for attenuation correction, using predefined attenuation maps, etc., to address this issue [62].

In spite of the challenges, there are many distinct advantages offered by a PET/MRI system over a PET/CT: it improves lesion detection in the brain, kidneys, liver, breast, and bone; it improves T staging of solid tumors by providing better soft tissue delineation; and it comparatively decreases radiation exposure to the patient and improves motion correction.

7.1.1 Specific Indications of PET/MRI in Clinical Oncology

Head and Neck Cancers

PET/CT is a well-established modality of choice for staging head and neck malignancies; its most important indication is in nodal staging and evaluation of distant metastasis. Most of the T staging can be effectively performed by clinical methods and endoscopic examinations. However, in few locations such as the pyriform sinus, floor of the mouth, and base of the tongue, it becomes difficult to evaluate T staging by only using clinical methods. Owing to excellent soft tissue discrimination, MRI is a magnificent tool for evaluation of lesion extent and local invasion. In this regard, PET/CT can be limiting. PET/MRI fusion thus provides better "T" and "M" staging in head and neck malignancies in a single imaging modality. However, concrete evidence-based data in this regard are lacking. Most literature published are small case series [62].

Liver Metastasis

Identifying liver metastasis is extremely important in various cancers. PET/CT is a common modality to assess liver metastasis. However, MRI has higher sensitivity and accuracy as compared to PET/CT [63]. It provides a better detection rate and diagnostic confidence, especially for metastasis of <1 cm size [64].

Brain Tumors

MRI provides excellent morphological information of brain pathologies. MRI/PET can better grade gliomas, provide better information regarding spread of the tumor along the white matter tracts, and is better for treatment response evaluation, as compared to PET/CT [65].

Prostate Cancer

PET/MRI may help in the precise mapping of a PET-positive lesion and scores over PET/CT in excellent anatomical localization of the lesion [66]. Carbon-11 (C-11) choline PET/MRI in 32 patients with prostate cancer showed better anatomical delineation of the lesions to the bone and pelvic organs or tissues by C-11 choline PET/MRI as compared with C-11 choline PET/CT [67].

Lung Cancer

PET/MRI has proven advantageous in T staging in cases of mediastinal involvement and chest wall infiltration [68]. It can be used as a one-stop imaging for evaluating brain metastasis during staging.

Breast Cancer

PET/MRI helps in evaluating the primary lesion and to look for distant metastasis. It scores over PET/CT in evaluating liver and brain metastases [69].

Bone and Soft Tissue Malignancies

It helps in identifying marrow-infiltrating lesions in sarcoma and multiple myeloma. It also helps in staging of the primary tumor [70].

Pediatric Malignancies and Lymphomas

It offers lower radiation exposure as compared to PET/CT. Special MRI sequences like diffusion-weighted imaging (DWI) help in detecting highly cellular lesions, and can thus act complementary to FDG/PET [71].

8 Therapeutic Nuclear Medicine in Oncology Practice

8.1 The Fundamental Principles of Radionuclide Therapy Using Unsealed Sources

In contrast to gamma rays utilized in diagnostic imaging, particulate ionizing radiations such as α, β, and auger electrons are used for therapeutic purposes in clinical oncology to delivery highly selective radiation doses to the diseased sites. Hence, this could be considered the fundamental difference between the radiopharmaceuticals tagged with a therapeutic radioisotope and those used for diagnostic purposes. Some of the commonly used therapeutic radionuclides with their physical characteristics are enlisted in Table 5.

Table 5 Therapeutic radionuclides

	I-131	P-32	Sm-153	Sr-89	^{177}Lu
Eβmax (MeV)	0.606	1.71	0.81	1.46	0.497
Eβmean (MeV)	0.190	0.70	0.23	0.58	0.165
Soft tissue range	0.6–2 mm	3 mm	0.6 mm	2.5	<1.5 mm
γ-Rays	364 keV (80%)	No	103 keV (28%)	910 keV (0.01%)	113 keV (6.6%), 208 keV (11%)
Half-life	8.02 days	14.3 days	1.9 days	50.5 days	6.7 days
Route of administration	Oral	Oral	IV	IV	Intravenous

9 Specific Indications in Clinical Oncology

9.1 Thyroid Cancer

Radioactive iodine (RAI) has been used over the last six decades in patients with differentiated thyroid cancer (DTC) in the post-total thyroidectomy setting. The reason for this is that follicular cells of the thyroid have sodium iodide symporters (NISs) that transport iodine with Na^+ across the basolateral membrane [72]. A human NIS is a glycoprotein containing 643 amino acids. The gene is located on chromosome 11. Well-differentiated thyroid cancer cells usually express NISs and, as a result, are able to concentrate RAI, thus enabling the use of RAI for ablative purposes [73]. Studies have shown that postoperative RAI use significantly improved disease-free survival (DFS) in patients with DTC [74]. RAI is administered to post-thyroidectomy patients with differentiated thyroid cancer. The indications for RAI administration can be one of the following: (1) remnant ablation, (2) adjuvant treatment, and (3) therapy of the metastatic disease.

9.1.1 Remnant Ablation

RAI is an effective modality in ablating remnant thyroid tissue in a postoperative bed as well as in destroying microscopic disease present in a post-thyroidectomy DTC patient. The rationale behind is to effectively use serum thyroglobulin as a tumor marker and detect disease recurrence. No standard definition of a successful ablation is available. Most groups, however, consider successful remnant ablation as no appreciable uptake in the thyroid bed in a diagnostic scan at 6–8 months after the therapy or, if appreciable, a percentage uptake <0.1% and/or a stimulated serum thyroglobulin (Tg) concentration <1 ng/mL [75]. The dose of RAI for remnant ablation has been a controversial issue. However, now, most authorities agree that a dose of 30–50 mCi of RAI is sufficient for successful remnant ablation [76]. The target for remnant ablation is usually low-risk patients. However, the latest guidelines by the American Thyroid Association (ATA) have questioned the need for remnant ablation in low-risk patients [77].

9.1.2 Adjuvant Therapy

By definition, adjuvant therapy is administered when there is a suspicion of residual microscopic disease being left out during surgery, or there is tumor spillage during surgery, to decrease the risk of future recurrence and improve disease-free survival. DTC patients with intermediate-risk features, such as locoregional nodal metastasis, tumor with extrathyroidal extension, or tumor with vascular invasion or with high-risk histology, are usually considered for adjuvant therapy. Adjuvant RAI therapy is associated with increased survival for intermediate-risk papillary thyroid cancer [78]. The usual dose of RAI for adjuvant therapy is 150 mCi [77].

9.1.3 Treatment of Metastatic Diseases

RAI is the treatment of choice for iodine-avid metastatic thyroid cancer. The most frequent sites of metastasis are the lungs and bones. Pulmonary micrometastasis responds extremely well to RAI treatment and should be treated every 6–12 months until complete resolution [79, 80]. The dose is 100–200 mCi or 100–150 mCi for patients aged 70 years or more. Bone metastasis can never be cured with RAI but significantly increases progression-free survival. RAI activity up to 200 mCi can be empirically administered [81] (Fig. 4).

9.1.4 Treatment for Iodine Refractory Thyroid Cancer

Iodine refractory metastatic thyroid cancer poses a unique therapeutic challenge to the clinician. The most accepted mode of treatment for these patients is by tyrosine kinase inhibitors [20]. However, these treatments carry several serious side effects. In this regard, somatostatin receptor (SSTR) expression in these patients and subsequent treatment with Lu-177-tagged peptide receptor radionuclide therapy (PRRT) have been explored in various case series and studies [82, 83], though, in our experience, high uptake to justify PRRT occurs in 15–20% of such patients.

9.2 Polycythemia Rubra Vera

Polycythemia rubra vera is a slow-growing tumor of the bone marrow erythroid lineage. The radionuclide traditionally used in this setting is the reactor-produced phosphorus-32. P-32 is a pure β-emitting radionuclide with a physical half-life of 14.3 days. The biological half-life of P-32 in the bone marrow is 7–9 days. The usual dose in polycythemia vera is 2–3 mCi/m^2 (5 mCi) or higher, i.e., 0.1 mCi/kg (max 7 mCi). P-32 gets incorporated into nucleic acids of rapidly proliferating cells, resulting in suppression of their growth. The patient is pretreated with venesection till hematocrit <42–47% and chemotherapy is usually discontinued for 1 week [84].

9.3 Bone Pain Palliation

There are many radiopharmaceuticals used for pain palliation in metastatic bone disease. Most of these radiopharma-

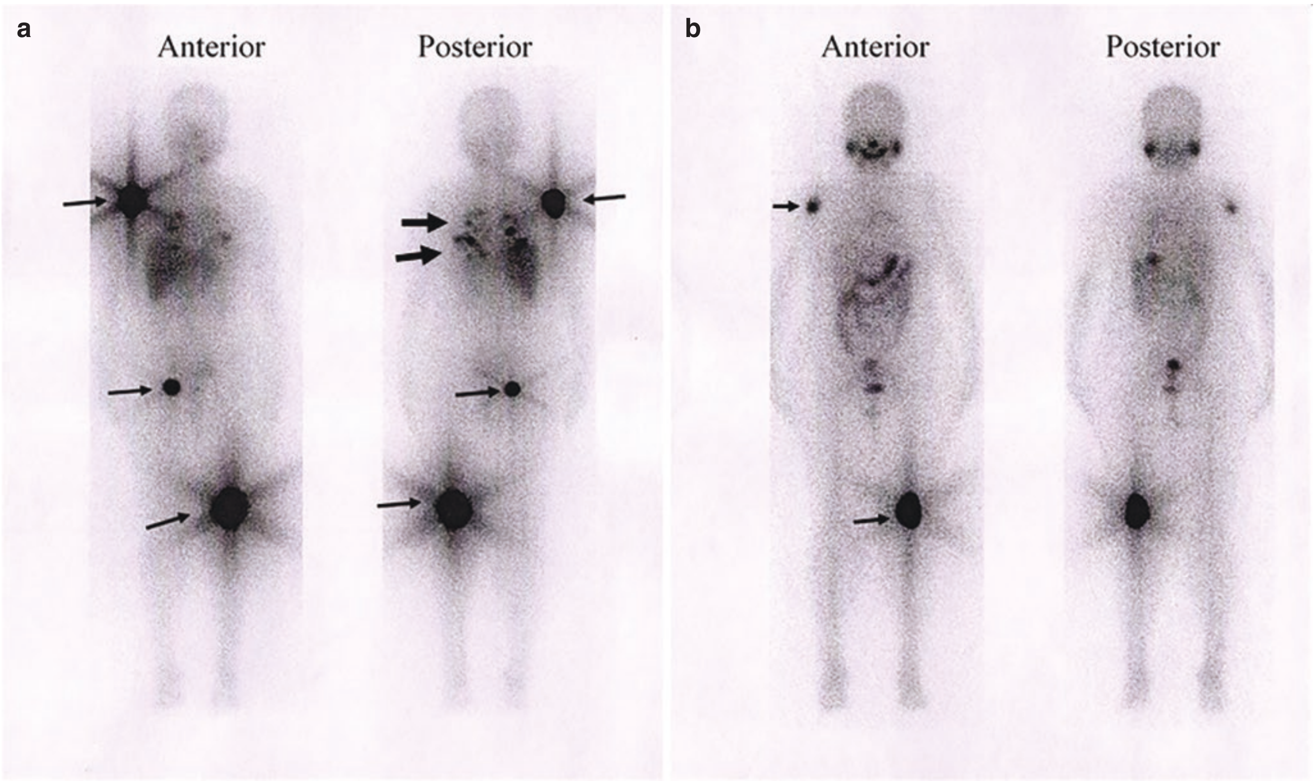

Fig. 4 A 31-year-old lady with a metastatic follicular variant of papillary thyroid carcinoma was treated with 205-mCi iodine-131. A post-therapy whole-body scan (image **a**) showed multiple sites of skeletal metastasis (thin arrows) and bilateral lung metastasis (bold arrows). A follow-up whole-body scan with 3-mCi iodine-131 performed after 1 year showed persistent uptake in the bones (arrows in image **b**). The patient was retreated with 200 mCi of RAI

ceuticals get incorporated into hydroxyapatite crystals and areas of high bone turnover, especially osteoblastic metastasis, and irradiate the area with β-radiation to alleviate pain. Some such agents are Sr-89 chloride, Sm-153 lexidronam, P-32-oral, and Re-186 etidronate [85]. In an Indian setting, Sm-153 EDTMP and Lu-177 EDTMP are the common radiopharmaceuticals used for this purpose in view of their easy availability through indigenous production.

9.4 Neuroblastomas

I-131-labeled MIBG is usually used as a diagnostic and staging agent for stage III/IV metastatic neuroblastoma (Fig. 5). Since I-131 is a β-emitter, this particular compound can be used for therapeutic purposes in metastatic and inoperable cases of a neuroblastoma. MIBG is a alkyl guanidine and a noradrenaline and guanethidine analogue. After intravenous (IV) administration, ^{131}I-MIBG is selectively concentrated in adrenergic innervations. It is taken up by the neuronal uptake 1 mechanism and stored in neurosecretory granules (adenosine triphosphate (ATP)-dependent process). Typical indications for I-131 MIBG therapy in neuroblastoma are metastatic MIBG-avid disease and unresectable tumor. The usual dosage of MIBG is 100–200 mCi, which is reduced in impaired renal function and myelosuppression. The specific activity of I-131 in ^{131}I-MIBG used for therapy should be 1.48 GBq/mg [86, 87].

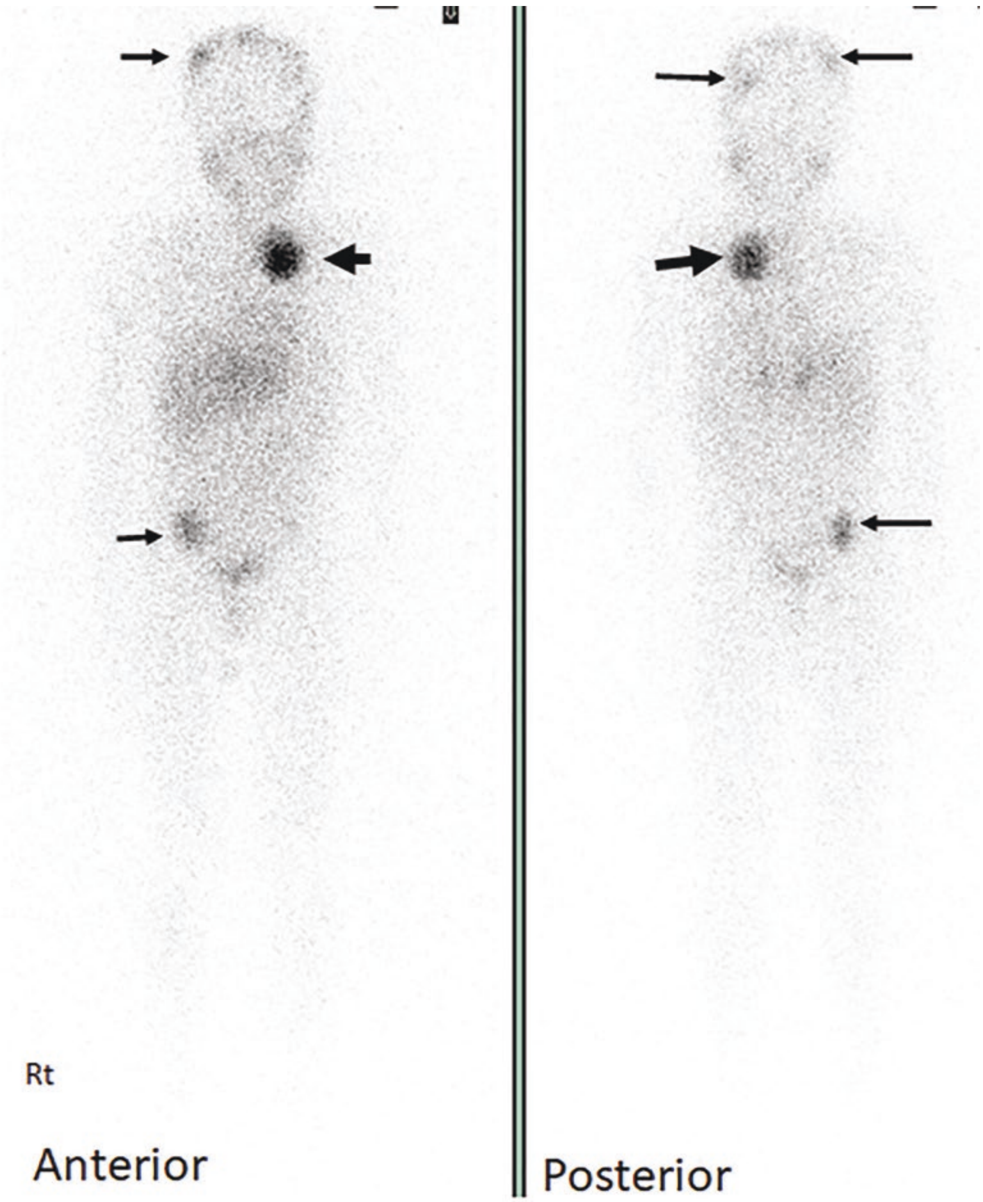

Fig. 5 A planar MIBG scan of a 7-year-old child with mediastinal neuroblastoma showing MIBG-concentrating lesion in the left upper thorax (bold arrow) and metastatic bone lesions in the skull and pelvis (thin arrows)

10 Theranostics

The term “theranostics” literally means coupling of therapy and diagnostics. The theranostic approach pairs diagnostic imaging and therapy using the same or similar molecule with different radiolabeling [88]. Sometimes in theranostics, the same molecule is administered at different dosages for diagnostic and therapeutic indications. Although this term has been used recently, the principle has been in practice for several years. In fact, I-131 can be considered as the first theranostic agent in nuclear medicine history, which was used for therapy and imaging in thyroid diseases. Presently used iodine-131 and lutetium-177 are both γ- and β-emitters, thus making them suitable for both imaging and therapy. Different isotopes of the same element with different characteristic of emission, like iodine-123 (γ-emitter) and iodine-131 (γ- and β-emitters), can also be used for theranostic purposes. The use of theranostic pharmaceuticals has been on the rise. Some of the commonly used theranostic pairs and their clinical uses are summarized in Table 6.

10.1 Receptor-Targeted Therapy in Theranostics

Two recent developments in receptor-targeted therapy have been the classical examples of the theranostic approach that has been used in clinical oncology.

Table 6 Theranostic pairs and their clinical uses

Theranostic molecule	Iodine	MIBG	SSA	PSMA ligands	Benzamide/ arylcarboxamide
Target	Thyroid cancer cells	Neurosecretory granules	SSTRs, especially the subtype SSTR2	PSMA	Melanin
Planar imaging/ SPECT	131I and 123I	$^{[131I]}$I-MIBG, $^{[123I]}$I-MIBG	SSA labeled with indium-111	$^{[123I]}$I-MIP-1072	$^{[123I]}$I-BA52

Chelator	DTPA/DOTA	DOTA	DOTA

10.1.1 Peptide Receptor Radionuclide Therapy (PRRT) in Metastatic Neuroendocrine Tumors (NETs)

This therapy consists of administration of a synthetic somatostatin analogue radiolabeled with a suitable β-emitting radionuclide, which specifically binds to SSTRs (mainly in grade 1–2 NETs) and are internalized thereafter to manifest the therapeutic action [89], thus enabling delivery of a high dose of cytotoxic radiation to tumor cells while sparing the normal tissues. Common radiopeptides used for PRRT are shown in Table 7. Of these, ^{177}lutetium-based radiopeptides are preferred in view of their lesser nephrotoxicity and hematotoxicity compared to the ^{90}yttrium-based radiopeptides owing to the harder β-energy of the latter.

Indication of PRRT:

- SSTR expressing metastatic or inoperable NETs, i.e., well to moderately differentiated midgut NETs [90] and bronchial NETs [91] (Fig. 6)
- Also in medullary thyroid cancer, pheochromocytoma, paragangliomas [92], and neuroblastomas [93]

10.1.2 ^{177}Lu-PSMA Therapy (Peptide Receptor Radioligand Therapy: PRRLT) in Metastatic Castrate-Resistant Prostate Carcinoma

Prostate-specific membrane antigen (PSMA) is a transmembrane glycoprotein receptor expressed on the surface of prostate cancer cells. It consists of 750 amino acids. It acts as an enzyme glutamate carboxypeptidase [94]. It is expressed at low levels in the normal human prostate epithelium. In prostate cancers cells, it is overexpressed almost 1000 times as compared to normal cells. It is expressed in virtually 90–95% of all prostate cancers [38]. The PSMA receptor, after binding to its ligand, undergoes endocytosis and gets internalized into an endosomal compartment inside the cell, which allows PSMA-labeled radioisotopes to be concentrated within the cell [95].

Of all the different PSMA-targeting molecules, small-molecule peptides have had the greatest success, due to their high-binding affinity to the PSMA receptor. This has paved the way for not only better PET imaging agents but also the development of targeted radionuclide therapy for men with prostate cancer. This targeted therapy for prostate cancer has, to date, predominately used lutetium-177 (Lu-177)-labeled PSMA peptides [96]. ^{177}Lu-PSMA is showing promise in the treatment of metastatic castrate-resistant prostate cancer (Fig. 7).

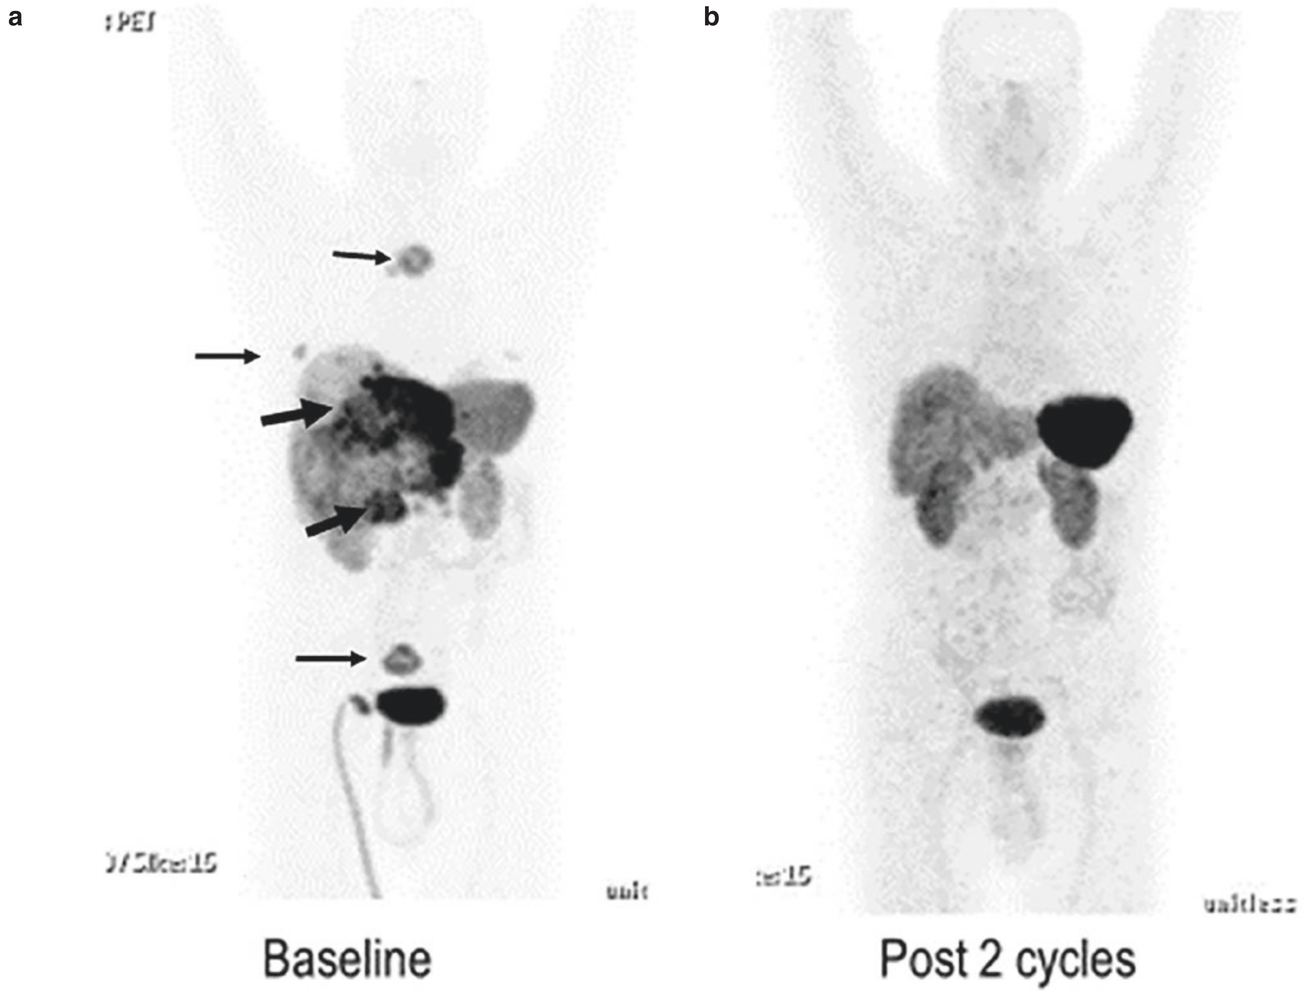

Fig. 6 Ga-68 DOTANOC PET images of a 68-year-old with metastatic grade III neuroendocrine tumor. Baseline maximum intensity projection (MIP) image (image **a**) showing somatostatin receptor expressing metastatic liver lesions, peripancreatic nodes (bold arrows), and skeletal lesions involving the ribs, sternum, and sacrum (thin arrows). MIP of the response assessment scan (image **b**) performed after 2 cycles of Lu-177 DOTATATE (PRRT) and capecitabine + temozolomide combination therapy showing near-complete resolution of the metastatic lesions

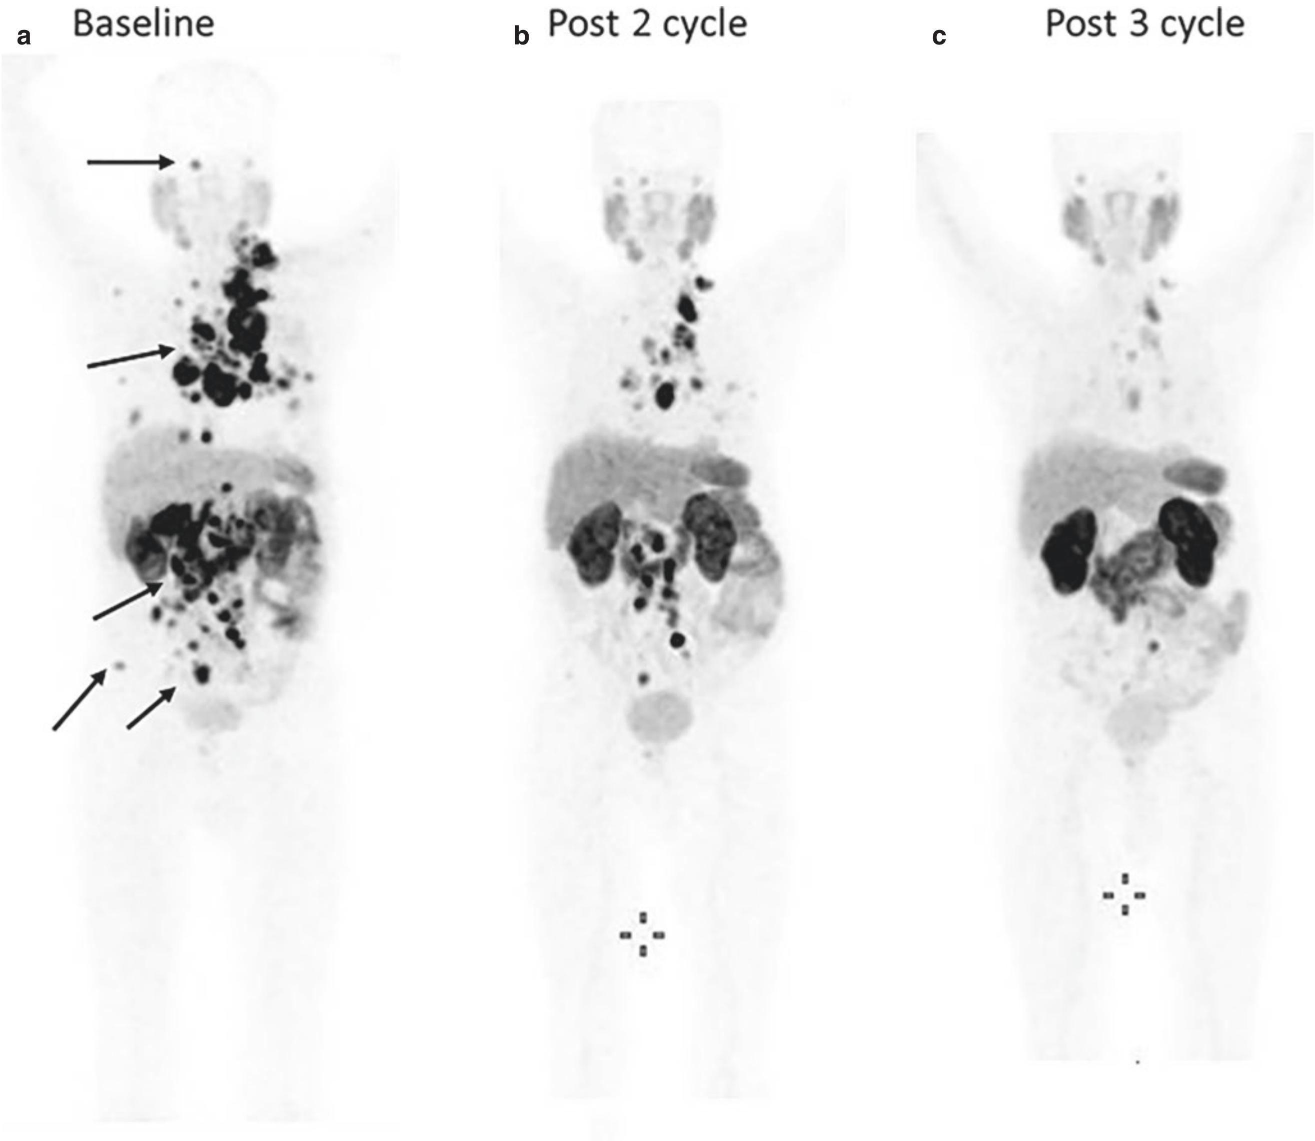

Fig. 7 Serial Ga-68 PSMA PET scan images of a 77-year-old man with metastatic castrate-resistant prostate cancer on Lu-177 PSMA therapy are shown. The baseline MIP image (image **a**) shows extensive nodal and skeletal disease (arrows). Images **b** and **c** showing gradual resolution of the PSMA-concentrating metastatic lesions after successive cycles of Lu-177 PSMA therapy

11 Alpha Therapy

The targeted alpha particle involves administration of a radionuclide, which undergoes alpha decay to treat cancer cells in close proximity. Targets include metastatic prostate carcinoma, leukemias, lymphomas, gliomas, melanomas, and peritoneal carcinomatosis [97]. The main advantages of alpha (α) emitters over the traditional β-emitting radionuclides are their extremely high linear energy transfer (LET), relative biological effectiveness (RBE), and lower intercellular range. Alpha particles are more likely than are β-particles to cause double-strand breaks to DNA molecules, which are harder to mend with DNA repair mechanisms, thus increasing the chance of cell death [97].

11.1 Applications

The following are the major areas where alpha radionuclide therapies have been ventured:

- Metastatic prostate carcinoma: 223-Radium chloride is a Food and Drug Administration (FDA)-approved agent used in castrate resistant prostate cancer (CRPC) with predominantly extensive bone metastases [98]. 225-Ac-PSMA-617 is also under trial for the same, and preliminary data are suggestive of excellent response in bone lesions and soft tissue lesions as well [99].
- Immunotherapy: Antibody agents tagged with 225Ac, 211At, 212Pb, and 213Bi have been tried [100].

- Peritoneal carcinomas: Treatment of peritoneal carcinomas has promising early results using α-emitting agents [100].
- Leukemia: Early trials of ^{225}Ac and ^{213}Bi have shown promise in leukemia patients [100].
- Melanomas: Phase I trials on melanomas with ^{213}Bi have shown promise [100].

12 Radioimmunotherapy

Radioimmunotherapy uses a radioactive isotope (often a β-emitter) chemically bound to a target-specific monoclonal antibody or fragment for cancer therapy. Thus, these radioimmunoconjugates can deliver a high dose of radiotherapy very precisely to the targeted cancer cells expressing the particular antigen [101]. To date, only two radioimmunotherapy molecules have been fully approved by the US FDA for commercial use: ^{90}yttrium ibritumomab tiuxetan (Zevalin) and (131) iodine tositumomab (Bexxar). Both of these compounds target the CD20 antigen expressed on normal and malignant B cells. These are approved for the treatment of refractory indolent B-cell lymphomas. The published literature suggests 20–40% complete response rates and 60–80% overall response rates in these patients. The toxicity profile is typically quite mild [102]. Rituximab has also been tagged with I-131 and Lu-177, and dosimetry data of these molecules have been published.

HER2/neu is overexpressed in approximately 20–25% of breast cancers [103]. HER2-positive breast cancers are known to be aggressive and are associated with poorer prognosis. Lu-177-trastuzumab is being used for specific tumor targeting in HER2-positive breast cancer patients [104].

Interventional Radiology in Oncology

Suyash S. Kulkarni, Nitin Sudhakar Shetty,
Mohd Shariq, and Kunal Bharat Gala

Abbreviations

ABC	Aneurysmal bone cyst
CT	Computed tomography
DEB	Drug-eluting beads
DSA	Digital subtraction angiography
DVT	Deep venous thrombosis
EBUS-TBNA	Endobronchial ultrasound-guided transbronchial fine-needle aspiration
GCT	Giant cell tumors
GGO	Ground-glass opacities
HIFU	High-intensity focused ultrasound
IR	Interventional radiology
IRE	Irreversible electroporation
MRCP	Magnetic resonance cholangiopancreatography
MRI	Magnetic resonance imaging
MWA	Microwave ablation
NSCLC	Nonsmall cell lung cancer
OA	Ophthalmic artery
PE	Pulmonary thromboembolism
PTBD	Percutaneous transhepatic biliary drainage
RFA	Radiofrequency ablation
RILD	Radioembolization-induced liver disease
SEMS	Self-expanding metallic stents
SVC	Superior vena cava obstruction
TACE	Transarterial chemoembolization
TARE	Transarterial radioembolization
TJLB	Transjugular liver biopsy
USG	Ultrasonography

1 Introduction

The term "Interventional Radiology," proposed by Dr. Alexander Margulisin in 1967 as a new subspecialty within the family of imaging sciences, involves the use of image guidance to diagnose and treat diseases in a minimally invasive way. Multiple medical conditions which previously required surgical operative procedures can now be managed in a minimally invasive manner with interventional radiology.

Interventional procedures are broadly divided into nonvascular (Fig. 1) and vascular (Fig. 2) interventions.

2 Image Guidance for Procedures

Image-guided procedures are performed widely for almost all organ systems to diagnose and characterize focal lesions and organ dysfunction. Ultrasonography (USG) is radiation-free, widely available, and the most commonly used modality for image-guided procedures since the images are in real-time and can be used for solid abdominal organs and lymph nodes of neck region [1]. Computed tomography (CT) is the preferred image guidance modality to target lung and bone lesions and biopsy small abdominopelvic lesions or collections requiring hydro-dissection. CT fluoroscopy reduces the patient's scan time and radiation dose and allows the operator to be present within the CT procedure room. Fluoroscopy is mainly used to perform a guided bone biopsy, and few nonvascular procedures like drainage obstructed biliary or urinary system. Digital subtraction angiography (DSA) is a minimally invasive test used to image the blood vessels when CT or MRI scanning is inconclusive. As the name suggests, bone and soft tissues (stationary) are digitally subtracted when contrast is injected into the vessels, rendering them visible because of the flowing blood. DSA is regularly used for any arterial or venous interventions.

Magnetic resonance imaging (MRI) is not extensively used as an ultrasound or CT scan for targeting a lesion. Breast, prostate, and bone biopsy is done using MRI at a few centers, and the instruments should be MR compatible.

Fusion imaging is used when images from one modality are superimposed on the images from another modality like ultrasound and CT fusion, ultrasound and MRI fusion, PET-CT fusion, PET-MRI fusion, or MRI-DSA fusion. This technique is used when the lesion is seen in one modality, and a different modality is used to target the lesion. For example, real-time USG-guided biopsy or RFA of lesions not seen on ultrasound but visible on CT, MRI, and PET-CT.

3 Patient Evaluation and Peri-procedural Care

Clinical evaluation of the patient includes obtaining a detailed history of the illness and performing a thorough clinical examination. The specific details that need to be asked include a history of allergies, previous reaction to contrast media, any illness such as diabetes leading to nephropathy, history of bleeding tendencies, and ongoing antiplatelet or anticoagulation medications.

3.1 Laboratory Tests

The following are a few relevant blood tests that are requested before IR procedures:

- Complete blood count
- Renal function tests: especially in CT-guided biopsy and interventions or when DSA is being performed, which would require the injection of iodinated contrast
- Prothrombin time, INR
- Fibrinogen when thrombolysis is planned
- 2D Echo before procedure requiring administration of chemotherapeutic drugs which are cardiotoxic like Doxorubicin

Antibiotic prophylaxis is started before a few procedures, per hospital policy and culture sensitivity reports. These include the following:

- Biliary procedures (Bilio-enteric fistula / anastomoses)
- Genitourinary procedures
- Drainage of suspected abscesses
- Embolization intended to invoke target ischemia/infarction (Single shot antibiotic)
- Ablation of tumors
- Biopsies (transrectal route)

If a patient is a known diabetic, sugar level optimization, and antidiabetic drug/dosage modification are done before the procedure. Those with a deranged renal function test would require optimization of serum creatinine. Adequate nephroprotection should be provided if iodinated contrast is being injected in such cases by proper hydration before, during, and after the procedure.

4 Non-vascular Interventions

4.1 Percutaneous Image-Guided Biopsy (Fig. 3)

General indications for a percutaneous image-guided biopsy are mentioned below. Few situations where nonpercutaneous biopsy is performed have been mentioned in the relevant section.

4.1.1 Indications

- Biopsy of a mass lesion for histopathological diagnosis of primary malignancy and immunohistochemistry adding to prognostication.
- Investigation of organ dysfunction, especially post-chemotherapy parenchymal dysfunction.

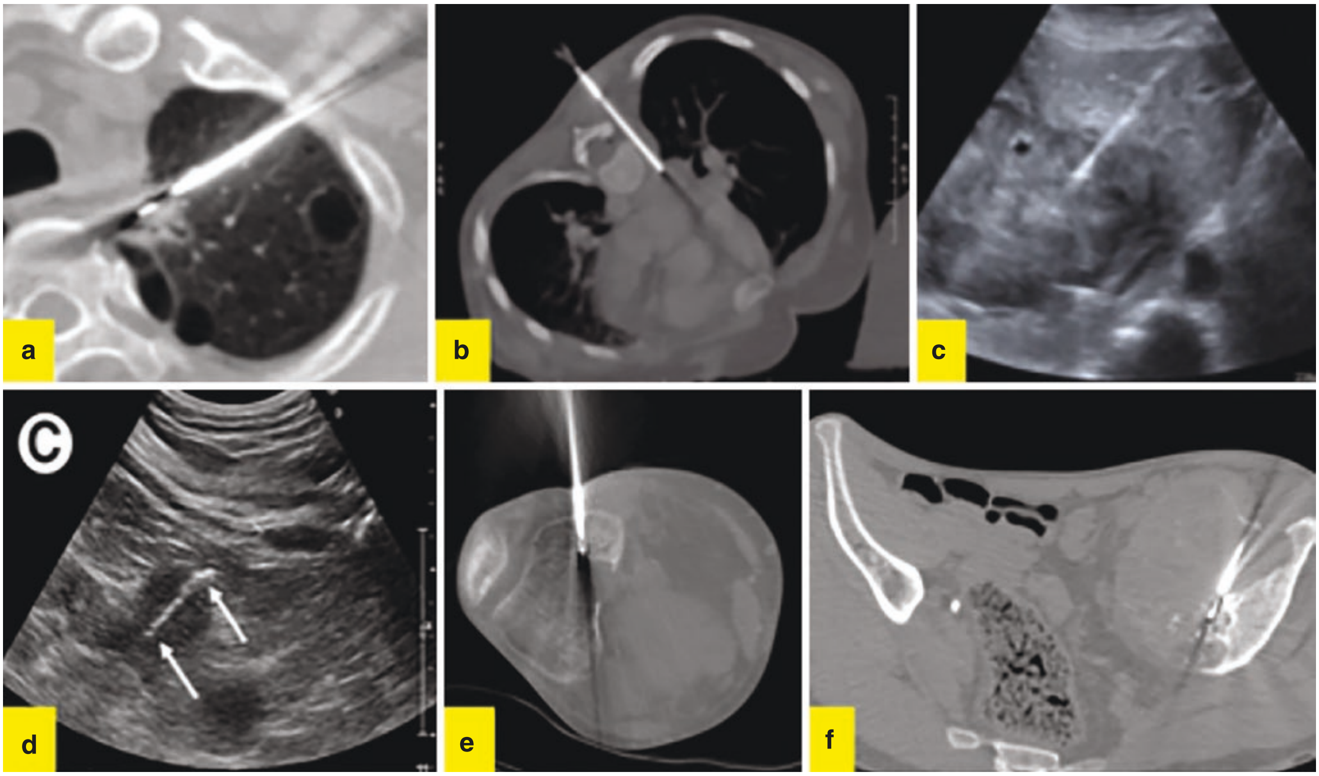

Fig. 3 Biopsies for (**a**) lung nodule, (**b**) subcarinal lymph node with an extrapleural approach using hydrodissection, (**c**) liver lesion, (**d**) renal lesion, (**e**) anteromedial approach for operable primary bone tumor, (**f**) and suspected chondrosarcoma

Table 1 Complications

All locations	Liver	Renal	Lung	Bone
Bleeding	Subcapsular hematoma	Hematuria	Hemoptysis	Osteomyelitis
Infection	Portal vein injury	Urinary leak	Pneumothorax	Fractures
Needle track seeding	Gall bladder injury	Urinoma	Hemothorax	Fat embolism
	Pneumothorax	Subcapsular hematoma leading to PAGE kidney	Air embolism	Neurological injury

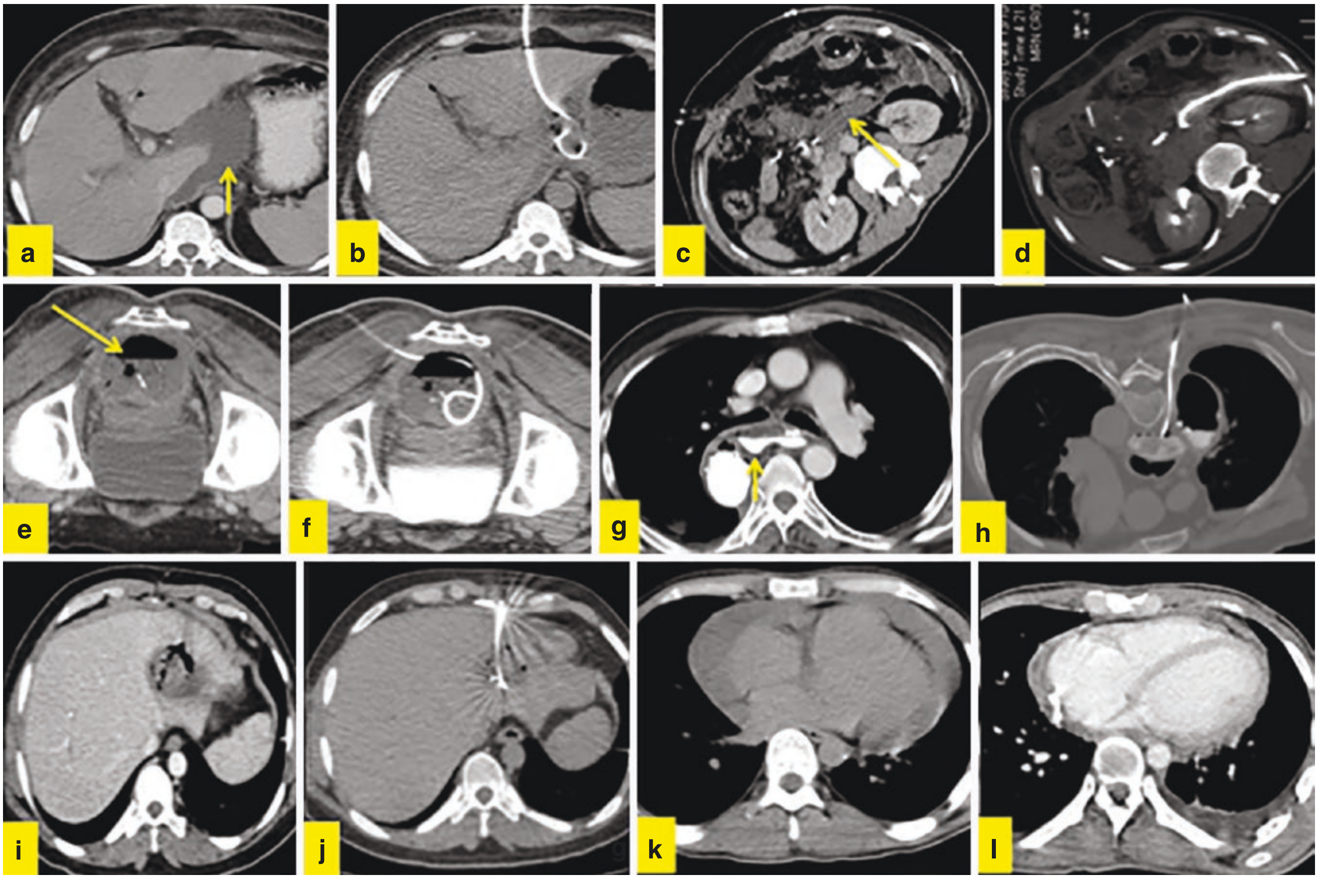

Fig. 4 (**a**, **b**) Lesser sac collection drainage, (**c**, **d**) post Whipple's collection drainage, (**e**, **f**) presacral collection drainage, (**g**, **h**) mediastinal collection drainage, (**i**, **j**) liver abscess pigtail, and (**k**, **l**) pericardial pigtail

- Biopsy of enlarged lymph nodes and metastases, thus allowing for accurate staging and altering management decisions.
- A sampling of infection for culture and sensitivity. Monitoring treatment response

4.1.2 Procedure Contraindications

- Coagulopathy (relative—can be done after correction of clotting factors).

4.1.3 Complications

Table 1 lists complications common to all locations and a few complications specific to particular sites.

4.2 Image-Guided Drainages (Fig. 4)

IR plays a significant role in the drainage of collections, which is a source of infection and septicemia, particularly in postoperative and post-chemotherapy patients.

- Postoperative collections—operative bed collections, anastomotic site leaks. Post operative leak - in iatrogenic biliary injury or ureteric injury
- Obstructive cholangitis
- Obstructive pyelonephritis
- Empyema/pleural effusion
- Pericardial fluid drainage. Indwelling catheter can be placed in cases with recurrent ascites

4.2.1 Pre-procedure

- The patient is started on broad-spectrum antibiotics.
- CT is the preferred modality for postoperative collections as ultrasound has limitations in penetrating gaseous interfaces. However, if a collection is well visualized on sonography, drainage can be done under ultrasound guidance.
- 16- or 18-gauge Trocar needle is routinely used for aspiration. If pus is obtained, a drainage catheter is placed within the collection.
- A sample of aspirated fluid is sent for gram stain along with culture and sensitivity.

4.2.2 Post-procedure

- Adequate care of the catheter is taken to avoid pull-out, and the drain output is measured both quantitatively and qualitatively.
- Antibiotics are changed as per the culture sensitivity report.
- Removal of catheter: The drainage catheter is removed when there is an overall improvement in the clinical well-being of the patient with the resumption of appetite and normalization of white cell count. On imaging, there should be a disappearance of the collection or a significant decrease in the size of the collection and the catheter output less than 10–15 mL daily [3, 4].

4.3 Tumor Ablation

Image-guided tumor ablation is a minimally invasive technique to treat focal tumors by inducing irreversible cell injury through various modes involving chemical injections and thermal or nonthermal energy (Fig. 5). These techniques are now widely used to treat liver, kidney, lung, and bone and soft tissue tumors. In some circumstances, especially for painful bony lesions, it is also finding wider application for pain palliation to improve the quality of life. Its advantages compared to surgical resection include less operative times, minimally invasive, lesser mortality and morbidity, lower cost, and the ability to treat patients who are unsuitable for surgery.

4.3.1 Thermal Ablation Modalities

Thermal ablation strategies increase or decrease the temperature of target tissues to induce irreversible cellular injury. Radiofrequency energy-based systems (RFA) and Microwave (MWA) remain the most widely used modality for the ablation of tumors present in any accessible site, but alternatives include high-intensity focused ultrasound (HIFU), and laser. Cryoablation, which uses hypothermia at freezing temperatures, is also used for focal thermal tumor ablation, especially for renal carcinoma and musculo-skeletal tumors [5].

Radiofrequency

Mechanism of action: When tissues are heated to >60 °C, irreversible cell death occurs due to coagulation necrosis. An electrical circuit is formed where the current loop comprises a generator, cables, electrodes, and body tissue as the resistive element [6] (Fig. 6). The RFA generator can be either monopolar or bipolar, a temperature-based system, or an impedance-based system.

Advantages: Cost effective.

Disadvantages: Heat sink effect, grounding pad burns.

Microwave

Mechanism of action: In microwave ablation (MWA), the inserted applicators function as antennae, and external energy is at 1000–2450 MHz, which causes rotation of the polar molecules. Frictional forces oppose the molecular rotations, and as a result, this converts the rotational energy into

Fig. 5 Modes of Ablation

NON-THERMAL
Irreversible Electroporation (IRE)

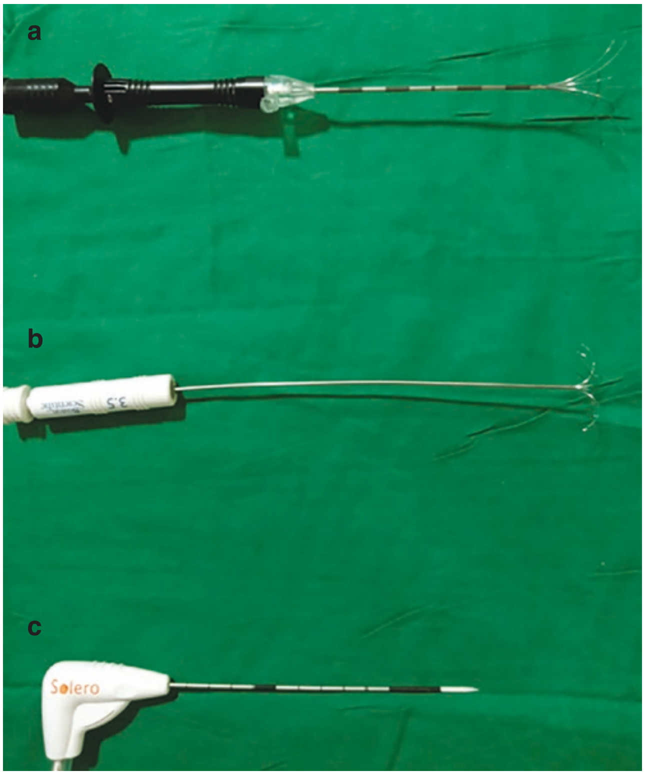

Fig. 6 (**a**, **b**) Radiofrequency ablation electrodes and (**c**) microwave antenna

heat. It can attain higher temperatures than RFA, reaching up to 123 °C.

Advantages: Microwaves readily penetrate through biological materials, including those with low electrical conductivity (e.g., lung, bone) and dehydrated or charred tissue. Microwave ablation reaches higher temperatures more efficiently, does not require grounding pads, and the ablation zone is not affected by surrounding blood vessels, resulting in the heat sink effect [7].

Disadvantages: Technical difficulty with surface lesions Table 2.

Cryoablation

Cryoablation refers to a thermal-based ablation modality that induces tissue injury and cell death using hypothermia at freezing temperatures. It destroys tissue through alternating sessions of freezing at very low temperatures, followed by tissue thawing. Cryoprobe is placed on or inside a tumor using appropriate imaging guidance, and liquid forms of inert gases like helium or nitrogen are circulated through the hollow cryoprobes, which results in cooling of the surrounding tissues to lethal temperatures.

Mechanism of action Cryoablation induces direct cellular injury by freezing and indirect injury through multiple mechanisms, including altering the cellular microenvironment. The temperature range of −20 to −40 °C can result in cell death [8]. Following are the mechanisms of cellular injury due to cryoablation:

Table 2 Comparison between RFA and MWA

	RFA	MWA
Mechanism	Electric current	Electromagnetic energy
Heating	Nonuniform	Uniform
Procedure time	More	Less
Intratumoral temperature	Less	More
Ablation zone	Unpredictable	Predictable
Heat sink effect	Present	Less susceptible
Periprocedure pain	More	Less
Lesion treated at one time	Single	Multiple
Ablation volume	Small	Large
Grounding pad	Present thus can lead to thermal burns	Absent
Abscopal effect	Yes	No

1. Osmotic dehydration causes high intracellular solute concentration leading to dysfunction of the enzymatic systems, damage to cellular proteins, and cell membrane injury.
2. Intracellular ice formation occurs, causing cell organelle and cell membrane injury.
3. Vascular injury consists of damage to the vessel wall [9].

Advantages: Decreased procedure-related pain, risk of thermal injuries to adjacent organs is less compared to hyperthermic ablations, improved real-time visualization of the ablated area in the form of ice ball, and ability to place multiple applicators simultaneously.

Disadvantages: Increased risk of bleeding.

Irreversible Electroporation

Percutaneous irreversible electroporation (IRE) is a relatively new ablation modality becoming increasingly popular due to its application in critical areas, which can be attributed to its nonthermal ablation modality.

Mechanism of action: Several microseconds to milliseconds of long pulses of electric current are passed into the target tissue, which generates an electrical field up to 3 kV/cm. This results in irreversible damage to the cell membrane leading to apoptosis and cell death.

Advantages: IRE appears to limit damage to more collagenous tissues and nerves and has the advantage of its application in thermally sensitive areas (e.g., in the pancreas near major bile ducts and large blood vessels) or neural structures [10]. At present, the maximum use of IRE has been in the treatment of locally advanced pancreatic cancer, and it is also finding wider application in hilar liver tumors.

Disadvantages: Cost, a technically more demanding procedure requiring simultaneous placement of multiple electrodes parallel to each other, risk of cardiac arrhythmias.

5 Vascular Interventions

A few terminologies about vascular interventions are mentioned later. The description of procedures is given in this chapter's relevant section.

Transarterial treatment includes those procedures which are performed through the arterial route. The term selective catheterization means cannulating an artery that is supplying the target area. Super-selective catheterization refers to advancing the catheter (usually a microcatheter less than 3 Fr in size) further distally into the artery as far as possible, which would predominantly supply the area of interest.

5.1 Trans-arterial Embolization (Angioembolization)

It involves angiography with embolization of the neoplastic vascularity for vascular tumors with embolic materials such as gel foam and PVA particles. It is mostly done for preoperative devascularization of tumors (e.g., juvenile nasopharyngeal angiofibromas) or to control bleeding from a ruptured tumor (e.g., hepatocellular carcinoma) or tumor infiltrating into a major artery (e.g., carotid blow out by lymph nodal mass).

5.2 Transarterial Chemoembolization

Transarterial chemoembolization (TACE) refers to local intra-arterial administration of chemotherapeutic agents followed by embolization of the tumor with permanent or temporary embolic material.

5.3 Transarterial Chemoinfusion

It is defined as the injection of chemotherapeutic drugs with or without ethiodized oil in the tumor feeding vessels without embolization.

5.4 Transarterial Radioembolization (TARE)

TARE involves the administration of the Yttrium-90 (Y90) radioisotope into the tumor-feeding arteries in the form of glass or resin spheres. Radioembolization is a misnomer as there is no or minimal embolic effect of the Y90 spheres. Thus, selective internal radiation treatment (SIRT) is a more appropriate term for this treatment.

6 Pulmonary Interventions

6.1 Endobronchial Ultrasound-Transbronchial Needle Aspiration (EBUS-TBNA)

Endobronchial ultrasound-guided transbronchial fine-needle aspiration (EBUS-TBNA) is a novel, minimally invasive method to sample mediastinal or hilar lesions using real-time guidance [11]. It involves targeting lymph nodes or other peribronchial lesions under ultrasound guidance (ultrasound probe mounted over the flexible bronchoscope, Fig. 7a) with a dedicated EBUS-TBNA needle.

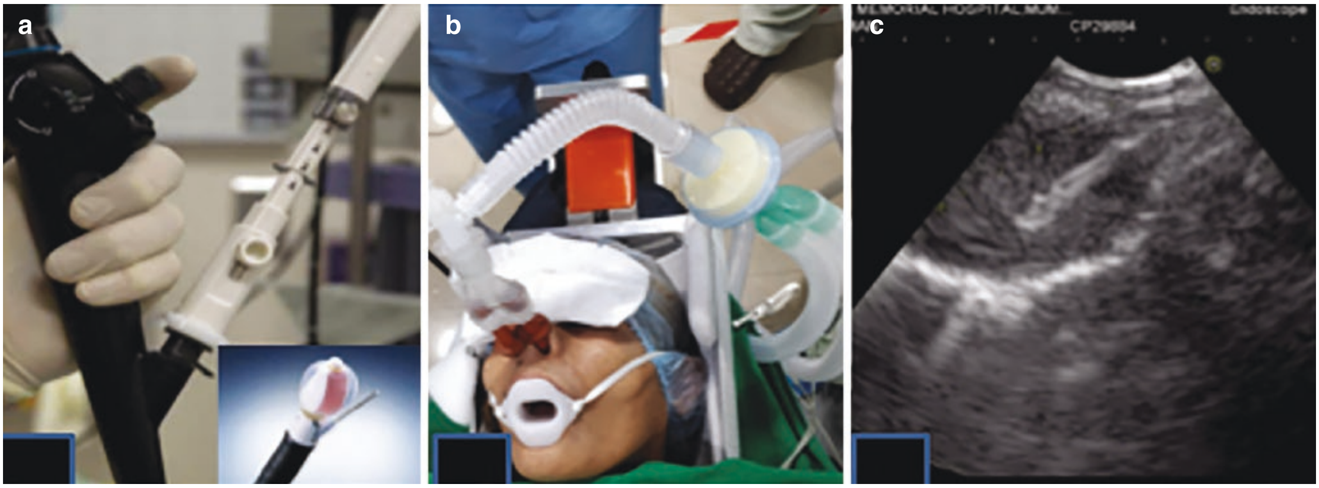

Fig. 7 (**a**) EBUS scope with the needle in the channel, (**b**) nasopharyngeal airway, and (**c**) endobronchial ultrasound image with the sampling needle in a lymph node

6.1.1 Indications

1. Mediastinal staging for nonsmall cell lung cancer (NSCLC).
2. To determine the cause/etiology of unexplained mediastinal lymphadenopathy.
3. As a research tool for tissue banking samples for later studies.

6.1.2 Advantages

- EBUS is a minimally invasive and safe procedure compared to mediastinoscopy.
- It can be performed on an outpatient basis using local anesthesia and conscious sedation.
- Real-time imaging allows the sampling of lymph nodes even smaller than 10 mm in the short axis and near major blood vessels (Fig. 7c).
- EBUS can access various levels of lymph nodes in the mediastinal and hilar lymph nodes with high sensitivity.

6.1.3 Complications

- No major complications.
- Reported minor complications are agitation, cough, hypoxia, laryngeal injury, fever, bacteremia, bleeding, and pneumothorax.

6.1.4 Disadvantages

The tissue cores are inferior to cores obtained from percutaneous biopsy

6.2 Ablation of Lung Tumors

Tumor ablation can be performed in patients with primary lung cancer and pulmonary metastases who are high-risk candidates for surgical resection.

6.2.1 Indications

- Stage I NSCLC
- Pulmonary metastases
- Residual/recurrent disease

6.2.2 Ablation Techniques

- Radiofrequency ablation
- Microwave ablation
- Cryoablation

6.2.3 Technique

- Imaging guidance with CT (Fig. 8a, b).
- RFA, MWA—ablation protocol as per device specifications.
- Surrounding GGO indicates adequate ablation (Fig. 8c, d).

6.2.4 Follow-Up

- PET avid lesions are followed up with locoregional PET, otherwise followed by CECT.
- Follow-up is done at 4-6 weeks, three-monthly for a year, and six-monthly subsequently.
- Response to ablation:
  - Less than a week: Ground-glass opacities (GGO) (the size of the lesion can be increased secondary to GGO)

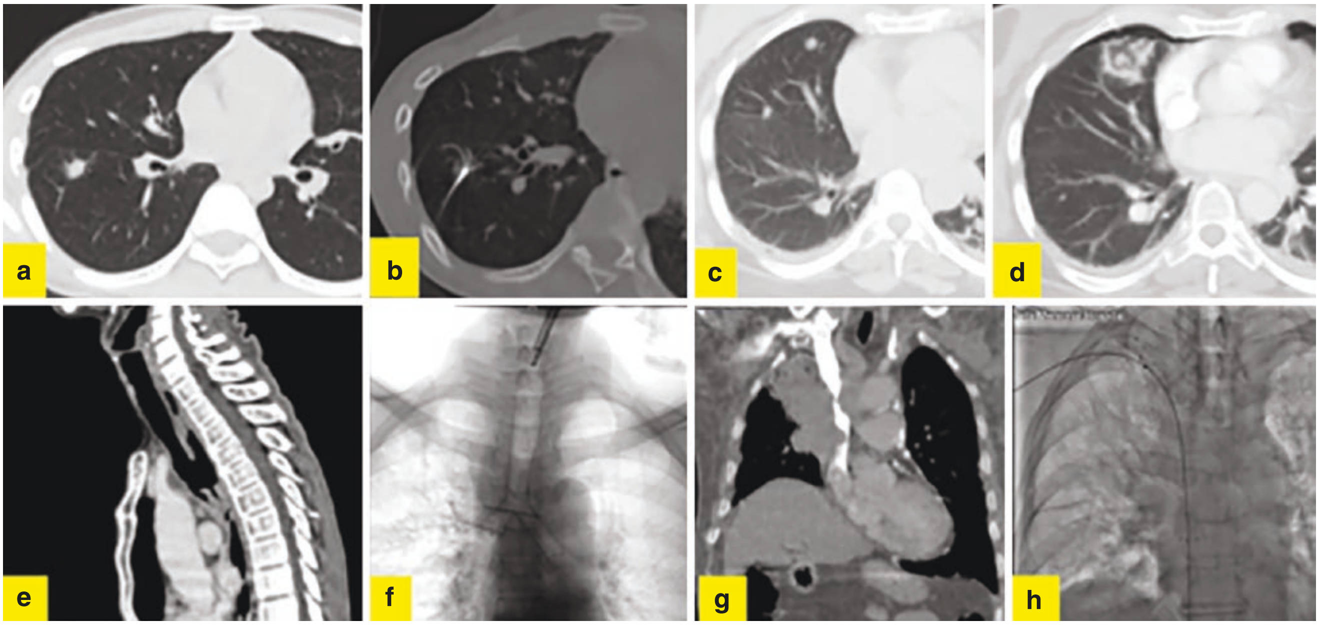

Fig. 8 (**a**, **b**) RFA of lung nodule. (**c**, **d**) Pre- and post-ablation image showing post-ablation surrounding ground-glass opacities. (**e**, **f**) Tracheal stenting for malignant trachea-esophageal fistula. (**g**, **h**) Stenting for SVC syndrome

Table 3 Complications of lung tumor ablation

Complication	Incidence (%)
Pneumothorax	11–52
Pain	0.6
Aseptic pleuritis	2.3
Hemorrhage	0.3–0.9
Bronchopleural fistula	0.3
Cavitation	14
Needle tract implantation	0.1
Infection—lung abscess	1.6

- One week to 2 months: Cavitation
- After 2 months, cavitation undergoes scarring
- At 6 months, minimal changes other than progressive involution of the cavity
- The lesion can show decrease in size or can disappear, can become fibrotic/atelectatic or cavitate

6.2.5 Complications (Table 3)

Outcome

The 3-year cancer-specific survival for stage 1 NSCLC ranges from 59% to 88% [12]. The 3-year cancer-specific survival rates in the cryotherapy, ablation, and surgical resection groups were 90.2%, 90.6%, and 87.5%, respectively [13].

6.3 Tracheal Stenting

6.3.1 Indications

- Central airway obstruction—The airway lumen can be compromised due to an intrinsic tracheal lesion or secondary to external compression.
- Malignant trachea-esophageal fistula [14].

The airway is best evaluated by computed tomography (Fig. 8e) and bronchoscopy to know the etiology, severity, and extent of the stricture and the dimensions of the airway, both proximal and distal, to the stricture.

6.3.2 Image Guidance and Procedure

Tracheal stenting is done under bronchoscopic and fluoroscopic guidance (Fig. 8f). A rigid bronchoscope/tracheoscope is introduced into the airway and placed beyond the vocal cords. Bronchoscope/Tracheoscope not only supports the stent system being introduced but also offers quick access to the airway by allowing ventilation and suctioning during and immediately after the procedure if required. A flexible bronchoscope is passed through this, and the site of stent placement is marked using fluoroscopic and bronchoscopic guidance. The tracheal stent(s) is deployed using the extrinsic skin markers as a reference under fluoroscopic guidance. If the stricture is tight, a guidewire may have to be passed beyond the obstruction, and a stent tracked over it to place it in the desired location.

In situations involving the distal carina and its bifurcation, a “Y”-shaped stent would be required compared to a single stent in case of stricture proximal to the carina.

6.3.3 Complications

- Bleeding
- Tracheobronchial injury
- Arrhythmias
- Stent migration
- Stent infection

6.4 Superior Vena Cava Obstruction

SVC obstruction (also known as SVC syndrome) results in significant narrowing of the SVC, resulting in reduced venous return to the right atrium. It can be caused by extrinsic compression by primary or metastatic tumors or enlarged lymph nodes compressing the superior vena cava (Fig. 8g), central venous access-related benign stenosis or occlusion, and postoperative changes leading to stenosis.

Contraindications to SVC stenting include severe cardiac ailment, coagulation disorders, and chronic venous thrombosis.

The procedure is done under DSA guidance. The narrowed SVC segment is balloon-dilated (venoplasty) to increase the lumen diameter in case of a benign stricture. If the diseased portion recoils or, in case of malignant obstruction, a stent is placed across the stricture to maintain the antegrade flow of blood (Fig. 8h) [15]. Thrombolysis can be considered prior to stenting in cases with bland thrombus in SVC due to chronic venous obstruction.

6.4.1 Complications

The complication rates of stenting for SVC obstruction are very low but include:

- Transient cardiac arrhythmias
- Stent migration
- Thrombus formation and stent stenosis/occlusion
- Migration of thrombus leading to pulmonary embolism
- Infection

7 Hepato-Biliary Interventions

7.1 Transjugular Liver Biopsy (TJLB)

Transjugular liver biopsy (Fig. 9a, b) is usually performed in patients with suspected diffuse parenchymal disease, such as cirrhosis, when a percutaneous biopsy is contraindicated.

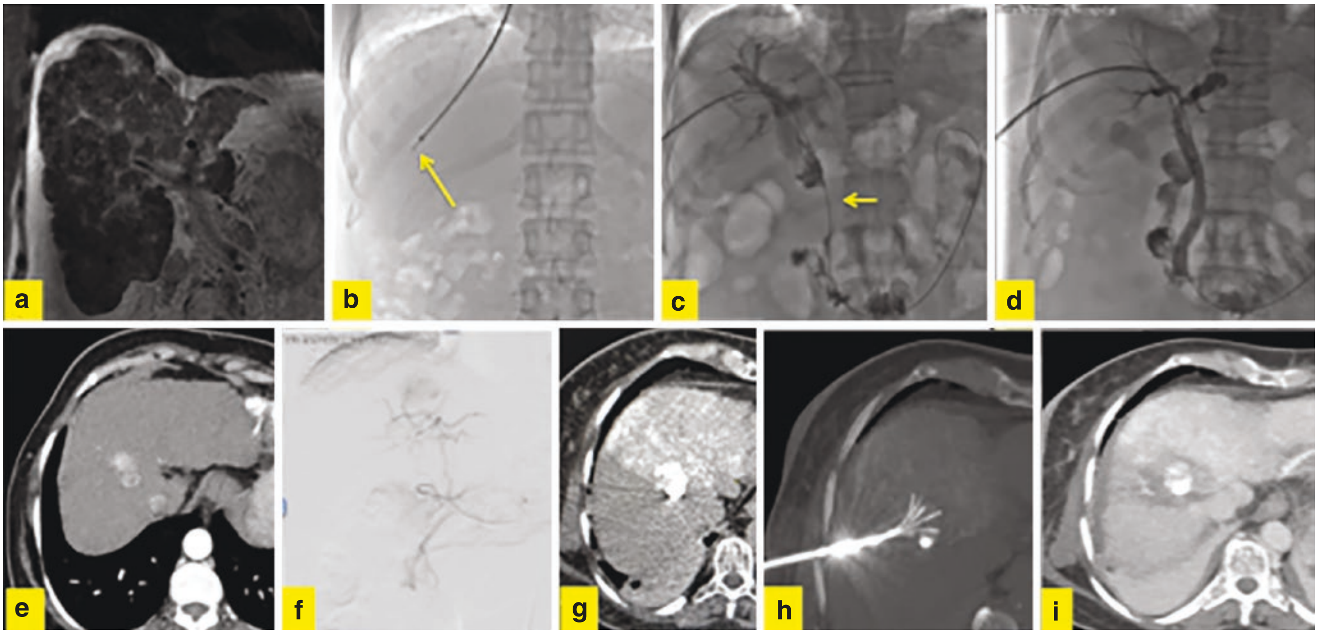

Fig. 9 (**a**) MRI showing diffuse liver disease with gross ascites. (**b**) Transjugular liver biopsy.(**c**, **d**) PTBD and metal stenting. (**e**) Solitary HCC in a k/c/o HCV related CLD. (**f**) cTACE. (**g**) Lipidol-coated liver lesion. (**h**) RFA. (**i**) Post ablation CECT showing the adequacy of ablation

7.1.1 Indications

1. Uncorrectable coagulopathy.
2. Gross ascites.
3. This procedure may also be performed in the absence of coagulopathy or ascites when wedged hepatic vein pressures have to be calculated.

The right internal jugular vein is accessed, and the right hepatic vein is cannulated using fluoroscopic guidance. A hepatic venogram is performed to confirm the identity and patency of the vein. Biopsy from the middle or left hepatic vein can also be performed. The optimal location to perform the biopsy from the hepatic vein is within 3–4 cm of the IVC. Biopsy from more peripheral areas in the hepatic vein risks capsular perforation and intra-abdominal bleeding. After the procedure, vital signs should be monitored for 4 h [16].

7.2 Percutaneous Transhepatic Biliary Drainage and Biliary Stenting

Obstructive jaundice can be caused by many conditions, including benign and malignant diseases. The common causes of malignant biliary obstruction include cholangiocarcinoma, pancreatic and gall bladder malignancies, metastatic lymphadenopathy, infrequently by the liver, and advanced gastric and duodenal malignancies. The essential purpose of biliary interventions in case of obstructive jaundice is to decompress the blocked biliary system and, if possible, to re-establish the physiological flow of bile from the biliary tree to the bowel. Percutaneous transhepatic biliary drainage (PTBD) decreases pain, jaundice, and cholangitis by relieving the obstruction. The drainage of the obstructed biliary system helps improve the liver function before planning for more definitive cancer-directed treatment in the form of surgery or chemotherapy.

7.2.1 Indications

1. Obstructive jaundice due to high biliary obstruction.
2. Failure of endoscopic drainage—percutaneous technique is successful in cases where an endoscopy has failed, as in the case of
    (a) Duodenal stricture
    (b) High or multiple blockages
    (c) Inability to traverse the biliary stricture
    (d) Failure to cannulate papilla
    (e) Post-surgical patients with altered anatomy or biliary enteric anastomosis
3. Biliary leaks.

7.2.2 Contraindications

1. Uncorrectable coagulopathy
2. Gross ascites
3. ECOG >2

Magnetic resonance cholangiopancreatography (MRCP) is essential to evaluate the extent and severity of biliary dilatation and the level of obstruction. PTBD and stenting (Fig. 9) are performed with ultrasound and fluoroscopy guidance. Percutaneous cholangiography is first used to evaluate the exact level and extension of the stenosis and to identify the most appropriate liver segments for drainage. A catheter can be placed for external drainage only or externally as well as internally into the duodenum (internal-external drainage) to bring down the bilirubin to an acceptable level for surgery. Self-expanding metallic stent(s) (SEMS) can be placed into narrow segments for inoperable cases [17, 18]. Patients undergoing metal biliary stenting are usually treated with palliative intent and are started on appropriate chemotherapy once bilirubin levels are reduced to <3 mg/dL.

8 Hepatocellular Carcinoma

Modified Barcelona Clinic Liver Cancer staging is most commonly used to stage and guide treatment for HCC.

8.1 Ablation

8.1.1 Indications

1. Hepatocellular carcinoma: Ablation is the first-line treatment for BCLC stage 0 (small HCC <2 cm), and the survival rates after ablation are similar to those after surgery for HCC <2 cm [19]. Ablation is also used in BCLC stage 1: HCC <3 cm and <3 lesions, bridge therapy to transplant while patients are on the waiting list, or as an alternative to surgery.
2. Colorectal liver metastases: Patients with liver-limited metastases and having five or fewer liver lesions can undergo ablation with curative intent.
3. Neuroendocrine liver metastases: Ablation can be done with curative intent for NET liver metastases. It also provides an option for symptom relief that decreases tumor burden, preserving most of the healthy liver, can be repeated and is associated with less morbidity than resection.

Ablation has the advantage of being a relatively low-risk, minimally invasive procedure for the treatment of focal liver tumors without significant damage to the surrounding liver tissue.

8.1.2 Ablation Modalities

1. Radiofrequency ablation
2. Microwave ablation
3. Cryoablation

For ablation results to be comparable with hepatic resection in terms of local tumor recurrence rates, a 360° 1-cm-thick tumor-free margin around each tumor should be obtained, which may require overlapping ablations [20].

Targeting the lesion for ablation can be performed with ultrasound or computed tomography (CT) and, less commonly, MRI depending on operator preference, local availability of dedicated equipment, and location of the lesion. Adjuvant techniques like hydrodissection, pneumodissection, artificial ascites, or pleural effusion can be used to separate and thus protect adjacent vital organs. It is a safe procedure with low rates of significant complications [21].

Complications include abdominal hemorrhage, hepatic abscess formation, hepatic infarction, biloma, and skin burns [22].

In patients with HCC, the combination of TACE and RFA is associated with significantly higher overall survival and recurrence-free survival compared to RFA alone, without a significant difference in major complications. This benefit is more critical in HCC larger than 3 cm in diameter (Fig. 9f–i) [23].

Follow-up of patients post-ablation is done at 6 weeks with laboratory investigations (CBC, LFTs, RFTs, and tumor markers) and imaging with multiphasic CECT or dynamic MRI liver.

8.2 Transcatheter Arterial Chemoembolization

Transcatheter arterial chemoembolization (TACE), in particular, has been widely performed in the treatment of HCC and is the recommended first-line treatment option for BCLC stage B patients.

TACE is the standard treatment for BCLC-B HCC patients who fulfill the following criteria: Child-Pugh A or B cirrhosis, patent main portal vein, less than 50% involvement of liver parenchyma by the tumor, ECOG <2, and patients willing for a follow-up. TACE can also treat some BCLC A patients who are unsuitable for ablative treatment or surgery.

Relative contraindications include extrahepatic disease, uncorrectable coagulopathy, biliary obstruction, or a comorbid illness like congestive heart failure. Doxorubicin, the most commonly used chemotherapeutic drug for TACE, needs caution prior to injection in patients with underlying cardiomyopathy or significantly reduced ejection fraction.

Absolute contraindications for TACE are Child C cirrhosis, ECOG >2, and main portal vein tumoral thrombosis

TACE can be of two types:

1. Conventional TACE: The chemotherapeutic drug emulsion is prepared using doxorubicin and iodized oil (lipiodol), infused into the tumoral feeding arteries. Cisplatin or mitomycin may also be given tailored according to the case. The infusion is followed by embolization of the

tumoral neovascularity. When the lesion shows complete coverage with lipiodol or if there is reflux of emulsion into nontarget branches, further injection of the emulsion is stopped (Fig. 9e, f).

2. DEB-TACE: DEB (drug-eluting beads) act as drug carriers and provide better drug delivery into the tumor with lesser systemic toxicity. Drug-eluting beads are loaded with doxorubicin for hepatocellular carcinoma and with irinotecan for DEBIRI-TACE of colorectal liver metastases.

8.2.1 Complications

1. Post embolization syndrome (nausea, fatigue, and low-grade fever)
2. Gastritis, cholecystitis
3. Hepatic decompensation (new-onset ascites, icterus)
4. Rare complications include ischemic bile duct injury, duodenal ulceration, and liver abscess formation

It has been found that the drug toxicity and systemic side effects are lesser in DEB-TACE compared to cTACE because of the sustained and controlled release of the drug.

8.3 Follow-Up

1. Follow-up after TACE includes a detailed clinical examination; serum AFP estimation CECT/MRI at 4–6 weeks to assess response. CECT or MRI can be done at follow-up after DEB-TACE; however, MRI is preferred after cTACE as lipiodol deposition makes it challenging to evaluate for residual enhancement.
2. If bilobar treatment was planned initially, the other lobe is treated in 3–4 weeks after repeating the LFTs.
3. If the follow-up imaging shows residual or recurrent disease or if there is raised serum AFP level, a repeat TACE is undertaken after a gap of 3–6 weeks following the previous session of TACE, only if the Child's status is A or B [24–26].

8.4 Selective Internal Radiation Therapy (SIRT) or Transarterial Radioembolization (TARE)

TARE involves delivering Y90 (yttrium 90) impregnated microspheres selectively through the hepatic artery to the tumor. The Y90 radioisotope is unstable and undergoes decay into the stable element zirconium-90 emitting beta particles, which induce direct destruction of cells of the target tumor. Currently, two Y90 products are commercially available: TheraSphere (glass microspheres) and SIR-Spheres (resin microspheres).

Patient selection for TARE requires history and physical examination. Patients with a poor general condition (ECOG score >2) or expected survival of less than 3 months and deranged liver functions are not candidates for TARE. Preprocedure imaging includes chest computed tomography (CT), either a multiphasic CT abdomen or dynamic magnetic resonance (MR) scan of the liver, and sometimes a bone scan.

Ideal candidates have HCC confined to the liver with a tumor comprising less than 70% of the liver volume. For patients with multiple tumors or HCC in both lobes, the liver function should be preserved for performing sequential treatments for both lobes. Patients with main portal vein thrombosis in whom TACE is contraindicated can be treated with TARE.

TARE requires a pretreatment angiography for accurate mapping of the hepatic vessels, extrahepatic tumoral supply, and the presence of shunting to healthy liver or lungs. Macroaggregated albumin (MAA) lung shunting study is performed before TARE to predict the lung shunt fraction (LSF) and minimize the chances of radiation-induced lung damage. In the ^{99m}Tc-MAA nuclear scan, 4–5 mCi of ^{99m}Tc-MAA is injected into the hepatic artery feeding the tumor, and a SPECT scan is performed. This test is performed to determine whether arteriovenous connections within and surrounding the tumor divert blood flow to the lungs. The administration of Y90 microspheres could thus enter the lungs and cause radiation pneumonitis when TARE is performed in cases with a high lung shunt fraction (>20%).

TARE has been evaluated to be useful in hepatocellular carcinoma (Fig. 10a–d), intrahepatic cholangiocarcinoma, neuroendocrine liver metastases, and colorectal liver metastases (Fig. 10e–h).

The advantages of TARE include cases where TACE cannot be done (e.g., those with portal vein thrombosis), elderly population, cases where TACE has failed, and patients with bilobar disease where more than five lesions are present. In patients with HCC, TARE showed to have a longer time to tumor progression than TACE, thus better serving as a bridge to liver transplant at centers with a long wait time [27, 28].

8.4.1 Follow-Up

The patients are usually followed up after 6 weeks when the clinical condition is assessed primarily for potential adverse effects. Laboratory investigations mainly involve monitoring the liver function tests and tumor markers for disease control (S.AFP, CEA). In the case of sequential bilobar treatment, the next session of TARE to the untreated lobe is performed 4–6 weeks after the first treatment. Imaging with either CT or MRI is usually performed at 6-month follow-up for radiological response assessment.

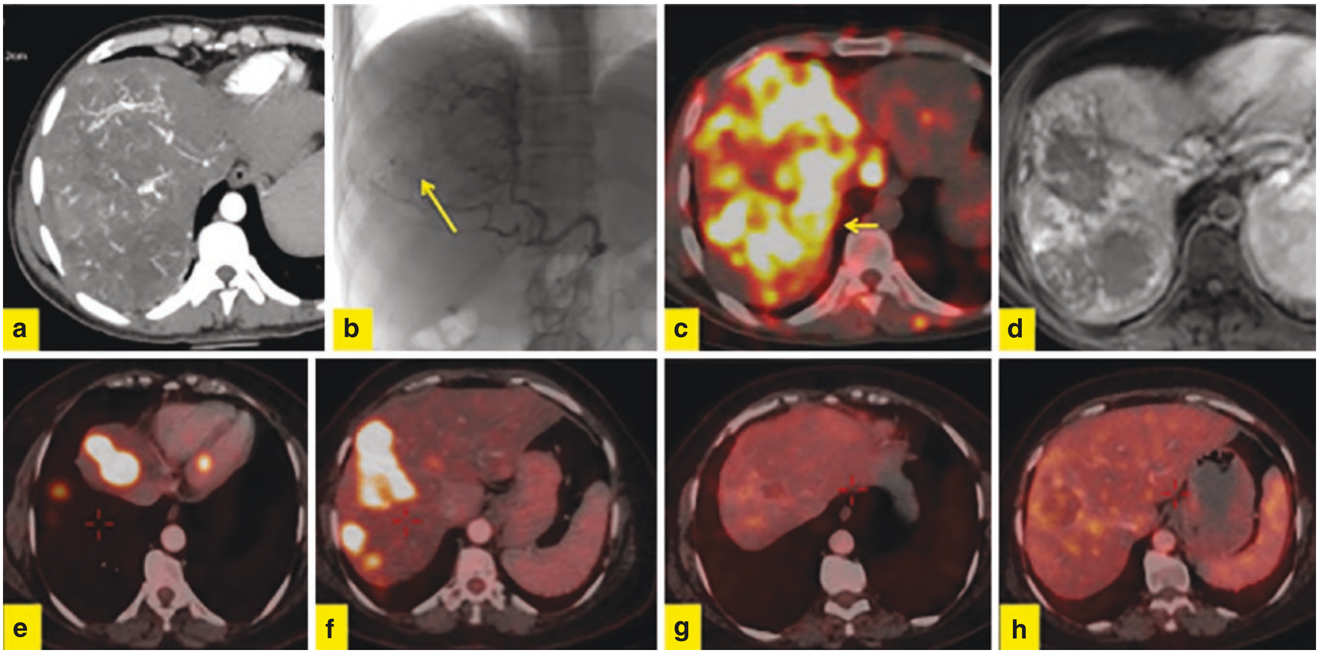

Fig. 10 (**a**) Large HCC invading the portal vein. (**b**) Hepatic angiogram and TARE. (**c**) Post TARE PET to look for drug distribution. (**d**) Follow-up CEMRI shows necrosis within the lesion. (**e**, **f**) Colorectal liver metastases refractory to systemic chemotherapy. (**g**, **h**) Post-radioembolization complete metabolic response on follow-up PET-CT

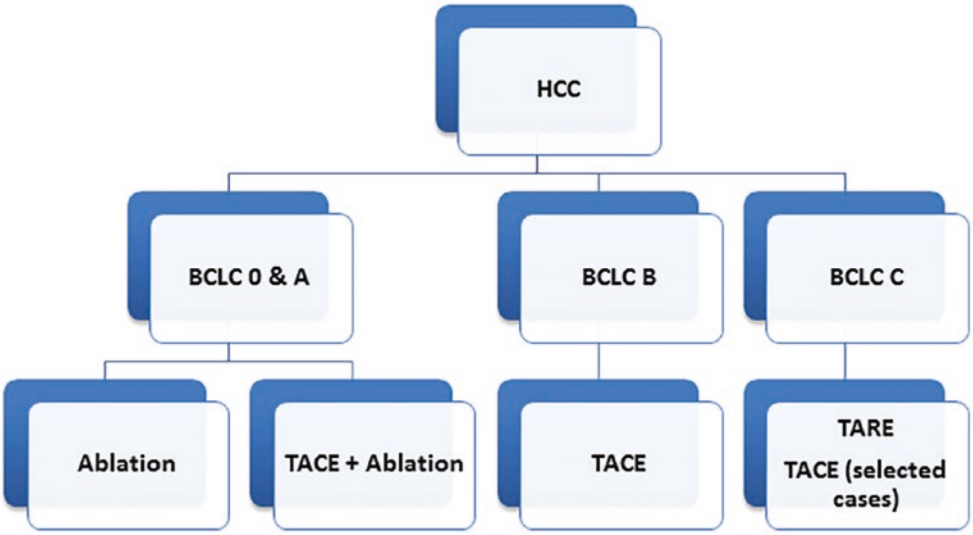
Fig. 11 Role of IR in the management of hepatocellular carcinoma



8.4.2 Complications

1. Mild clinical side effects after radioembolization include abdominal pain, nausea, vomiting, fatigue, and fever, which usually occur within 4–6 weeks.
2. More severe complications (1–3 months after radioembolization) include gastric ulceration, pancreatitis, radiation pneumonitis) due to nontarget deposition of radioactive beads and liver decompensation.
3. Excessive irradiation of healthy liver parenchyma leads to radioembolization-induced liver disease (RILD), which is thought to be a veno-occlusive disease/sinusoidal obstruction syndrome [29].

The role of IR in managing hepatocellular carcinoma is presented in Fig. 11.

9 Genitourinary Interventions

9.1 Transjugular Renal Biopsy

Transjugular renal biopsy is usually performed in patients with the suspected renal parenchymal disease when a percutaneous biopsy is contraindicated.

9.1.1 Indications

1. Coagulopathy
2. Gross ascites

The renal vein is accessed via the transjugular route, similar to the TJLB procedure described in the previous section. A renal venogram is performed to confirm the identity and patency of the vein, and the biopsy is done with the biopsy gun provided in the TJRB set.

Complications can include persistent hematuria and perinephric hematoma.

9.2 Percutaneous Nephrostomy and Antegrade Ureteric Stenting

It is a procedure in which an external drain is placed in the renal pelvis to relieve the renal pelvis of any obstructive symptoms (Fig. 12a). It could be later converted into internal ureteral drainage by placing plastic (Fig. 12b) or metallic stent. Metallic stents, which can be retrievable or nonretrievable, may be more useful in cases of inoperable malignant strictures for long-term palliation of obstructive uropathy.

9.2.1 Indications

1. Obstructive uropathy
   (a) Extrinsic compression: lymph nodal masses, adnexal masses
   (b) Intrinsic: tumor
   (c) Postoperative stricture
2. Urinary diversion
   (a) Treat urine leak or fistula for postoperative patients
   (b) Decompress urinoma
   (c) Pyelonephritis
3. Access to percutaneous intervention
   (a) Antegrade ureteral stenting
   (b) Stricture dilation

9.2.2 Procedure

Depending on the patient's comfort, the procedure is performed with the patient in a prone, prone oblique, or lateral position. Regular monitoring of the vital signs is recommended during the procedure. The skin is cleaned with an antiseptic solution and draped to maintain the sterility of the procedure.

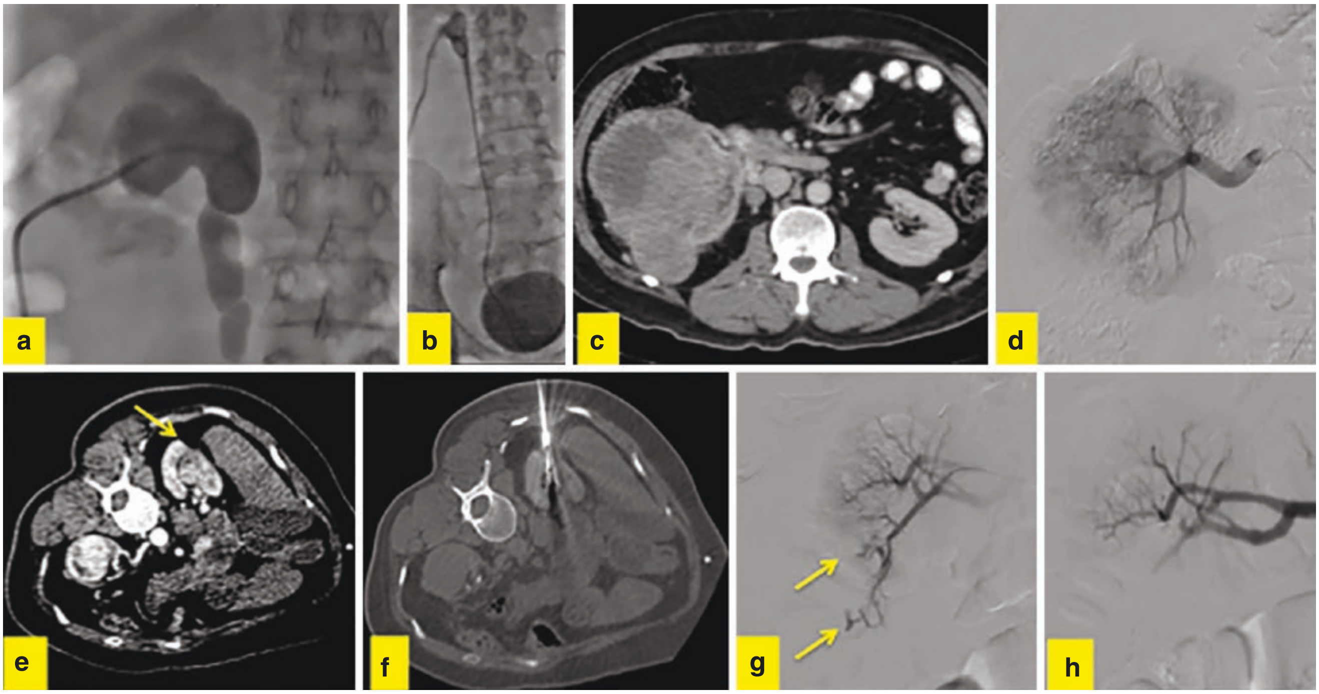


Fig. 12 (**a**, **b**) PCN with antegrade DJ stenting. (**c**, **d**) Metastatic RCC with severe hematuria for angioembolization. (**e**, **f**) RFA for RCC in a k/c/o VHL. (**g**, **h**) Post partial nephrectomy hematuria—coil embolization for pseudoaneurysms

9.2.3 Medications

Preprocedure antibiotic prophylaxis and pain medication is given.

9.2.4 Technique

The procedure is performed under sonography and fluoroscopy guidance.

Sonography is useful when the collecting system is dilated, lower/mid pole calyx is targeted, and an external drain is placed. Fluoroscopic guidance is preferred to puncture the calyx during PCN for an undilated pelvicalyceal system, as in case of a urine leak due to postoperative ureteric injury.

Antegrade ureteric stenting can be done via the access taken for percutaneous nephrostomy after crossing the obstruction with a catheter-guidewire combination [30]. If a ureteric stent is placed for <6 weeks, a polyurethane stent (JJ or DJ) stent is considered, while a silicone ureteric stent can be retained until 6 months without exchange. However, if there is repeated blockage of ureteric stents due to tumor compression or infiltration, a metal stent may be placed in the ureter. Plastic stent exchange needs to be done every 3-4 months to prevent encrustation.

9.2.5 Complications

- Bleeding
- Bowel injury and peritonitis
- Urine leak

9.3 Renal RFA

Renal carcinoma accounts for approximately 4% of all malignancies, and surgical resection remains the standard of care for renal tumors. However, the thermal ablation of a renal tumor can be an alternative treatment modality due to its minimally invasive nature.

9.3.1 Indications

International consensus panels support the following indications for ablative therapy of a small renal tumor that is less than 4 cm (T1a disease)

- Comorbidities that preclude surgery
- Comorbidities that preclude general anesthesia
- Require conservation of renal parenchyma as in case of solitary kidney or renal insufficiency
- Predisposed to multiple tumors in the same kidney (Von Hippel–Lindau syndrome)

9.3.2 Ablation Techniques

Thermal

1. Radiofrequency ablation (Fig. 12e, f)
2. Cryoablation
3. Microwave ablation

RFA and cryoablation are most commonly preferred for the ablation of renal tumors. Cryoablation is preferred in the case of centrally located tumors since it is possible to monitor the iceball formation and prevent damage to the pelvicalyceal system compared to RFA. For peripherally located lesions, both cryo and RFA may be preferred.

Procedure

USG or CT is used to guide the placement of an electrode or applicator. Contrast-enhanced ultrasound (CEUS) or contrast-enhanced CT can be used to aid tumor visualization. Applicators are placed in such a way that the ablation zone covers the entire volume of the tumor, including a margin of normal parenchyma. Overlapping ablation may be required to achieve complete ablation. Pyeloperfusion (cold saline for RFA and warm saline for cryoablation) is performed if a tumor is less than 1 cm from the ureter to prevent thermal injury to the pelvicalyceal system. Hydro dissection with 5% dextrose is done to displace and avoid bowel injury.

Adjuvant Techniques in Renal Tumor Ablation

- In cases with lesion >3 cm, angioembolization is done before ablation to reduce the size of the lesion and also to reduce the risk of bleeding as RCCs are hypervascular tumors.
- In cases with small lesions, preliminary angiography and lipiodol infusion can be done to enhance lesion visibility and thus improve targeting while ablation [31].

Complications

- In 80% of cases, fever or flu-like symptoms (post-ablation syndrome) develop.
- The majority of ablative complications are related to perinephric hematomas and transient hematuria.
- Ureteral strictures and large hematomas are rare. Urinary leak.

Outcomes

In the appropriately selected patients with stage T1a renal cell carcinoma, ablation is an effective treatment option that provides a 5-year efficacy of 97.0% and 5-year recurrence-free survival of 100%. The 5-year overall survival is 97.8%, with a complication rate of 6% [32, 33].

Follow-up interval and modality: Contrast-enhanced cross-sectional imaging follow-up with either CT or MRI at 1, 3, 6, and 12 months after RFA [34].

9.4 Renal Angioembolization

9.4.1 Indications

- Hematuria: postoperative (partial nephrectomy—Fig. 12g, h), post-biopsy.
- As an adjunctive procedure before ablation to reduce size and vascularity.
- Pre-operative devascularization to reduce intraoperative blood loss.
- Palliative to alleviate symptoms of pain and hematuria (Fig. 12c, d) [35].

10 Other Interventions

10.1 Central Venous Access

Image-guided percutaneous central venous access is defined as placing a catheter with its tip in the cavoatrial region or right atrium with the assistance of real-time imaging.

The sonography and fluoroscopy-guided central venous catheter insertion are faster, safer, and better than relying solely on anatomic landmarks.

Central venous catheters can be one of the four types [36]:

1. Peripherally inserted central catheters (PICC)
2. Temporary/nontunneled catheters
3. Permanent/tunneled catheters
4. Implantable ports

Peripherally inserted central catheters (Fig. 13a) are like long intravenous cannula. They extend from the puncture site up to the cavo-atrial junction. The PICC may have one to two lumens and range from 4- to 7-Fr. They are inserted from an upper arm vein, and indications include the following:

- Infusion of chemotherapy
- Infusion of intravenous fluids
- Infusion of blood products
- Infusion of total parenteral nutrition
- Blood sampling

Temporary/non-tunneled catheters (Fig. 13b) are commonly inserted through the internal jugular, made of polyurethane, and range from 6 to 13 Fr in size. They are suited for the delivery of medications, central venous pressure monitoring, and short-term dialysis. Indications include

- Infusion of intravenous fluids
- Infusion of blood products
- Infusion of total parenteral nutrition
- Blood sampling
- Mahurkar catheter—stem cell harvesting

A permanent/tunneled catheter (Fig. 13c) is a central venous catheter that traverses through a subcutaneous tract before entering the access vein. Tunneled catheters are preferred when central venous access is required for more than 2 weeks [36]. The catheter is tunneled subcutaneously for 10–15 cm before entry into the access, preferably the internal jugular vein.

A polyester cuff on the shaft of the catheter provides the catheter security to the subcutaneous tissues, which become incorporated within the tissues.

The advantages of these catheters are decreased risk of infection, reduced risk of inadvertent removal, improved cosmetic appearance, and patient comfort. Indications are

- Infusion of chemotherapy
- Infusion of intravenous fluids
- Infusion of blood products
- Infusion of total parenteral nutrition
- Blood sampling

A subcutaneous infusion port (Fig. 13d) consists of a tunneled central venous catheter that terminates in a subcutaneous pocket where a self-sealing reservoir is implanted [36]. They consist of a single or dual-lumen reservoir hub attached to the catheter. This reservoir hub is implanted in the arm or chest, and the catheter is tunneled to the vein accessed. The port can be accessed by Huber needle. These catheters are used for long-term access, such as for chemotherapy regimes. They have a lower rate of malfunction and symptomatic complications [37] and better cosmetic results. Of all the central venous catheters, ports have the lowest incidence of infection because they are entirely buried beneath the skin.

10.1.1 Complications

- Hematoma
- Cardiac arrhythmias
- Pneumothorax
- Air embolism
- Catheter-related infections
- Venous thrombosis
- Catheter tip migration
- Catheter fracture
- Catheter occlusion/fibrin sheath formation

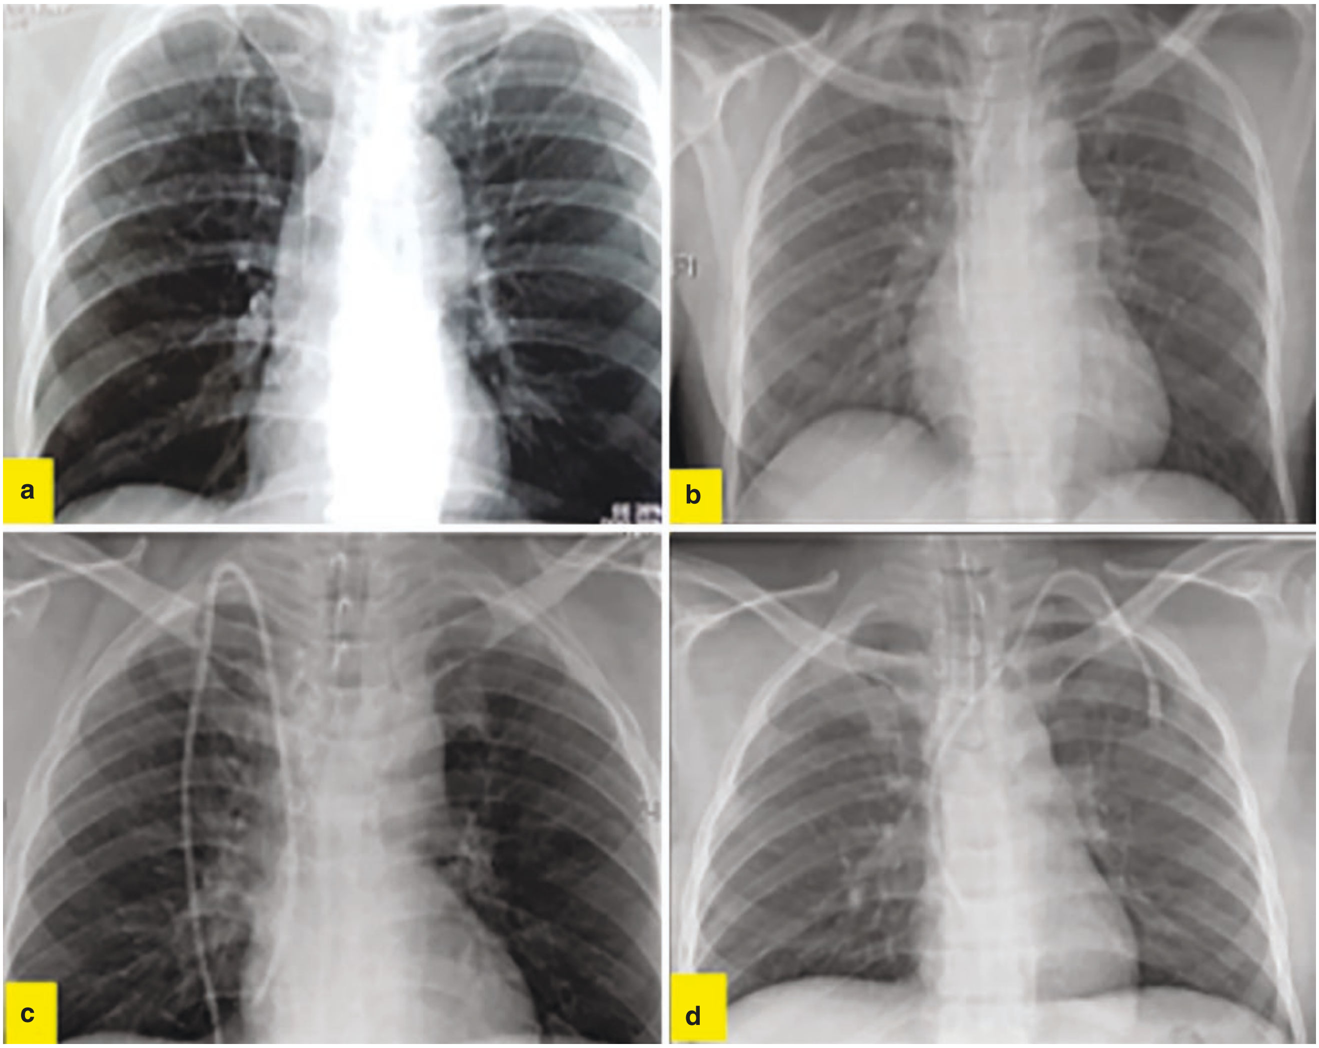

Fig. 13 (**a**) PICC. (**b**) Central line. (**c**) Hickmann. (**d**) Port insertion

10.2 Bone and Soft Tissue Interventions

Ablation, as a minimally invasive treatment modality, has emerged as an alternative to surgery in the management of select tumors of the bone and soft tissues.

10.2.1 Indications

1. Curative treatment for primary bone tumors—osteoid osteoma, chondroblastoma, and osteoblastoma. With the clinical success of ablation being 87–100%, ablation is now considered the gold standard in the treatment of osteoid osteoma (Fig. 14a–d).
2. Palliative treatment of painful bone metastases. Ablation is frequently combined with cementoplasty for pain palliation for weight-bearing bones. Angioembolization can be done before ablation and cementoplasty for vascular metastases like renal carcinoma and thyroid carcinoma (Fig. 14e–i).
3. Palliation of symptoms such as pain in case of nerve involvement or restricted range of movement in cases of fibromatosis (Fig. 14j–m).
4. It can sometimes be used for curative treatment of malignant bone tumors that have a postoperative recurrence and are not candidates for resection [2, 38].

10.2.2 Ablation Modalities

- RFA is the treatment of choice for osteoid osteoma.
- Minimal data is available on MWA and cryotherapy of bone tumors.
- It is mainly done under CT guidance with the resolution of clinical symptoms as an indicator for complete ablation.
- HIFU is used for painful bony metastasis.
- MRI is used in some centers for ablating tumors of the spine. However, this setup would be expensive and requires MRI-compatible instruments [39].

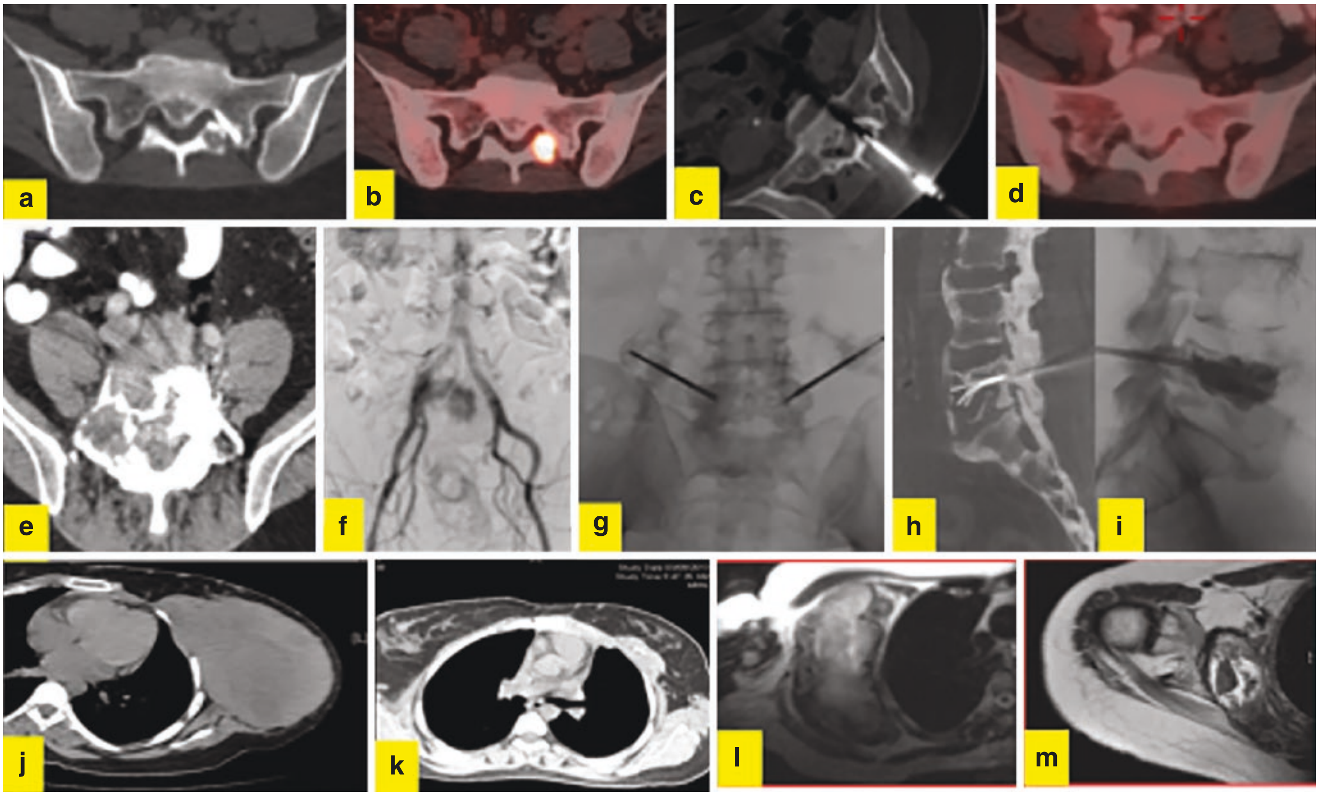

Fig. 14 (**a**–**d**) RFA of sacral (S2) osteoid osteoma. (**e**–**i**) Painful vertebral metastases, angioembolization followed by ablation and vertebroplasty. (**j**–**m**) Ablation for fibromatosis with post-procedure follow-up

10.3 Percutaneous Vertebroplasty

Percutaneous vertebroplasty is a therapeutic, image-guided, minimally invasive percutaneous procedure that involves an injection of radiopaque cement into a painful vertebral body to relieve pain and provide stability. Percutaneous kyphoplasty is a technique whereby expandable balloons are used to restore the collapsed vertebra's height before the cement injection.

10.3.1 Indications

- Painful osteoporotic vertebral compression fractures.
- Painful vertebrae due to malignant infiltration by multiple myeloma, lymphoma, and metastasis.
- Painful vertebrae due to aggressive primary bone tumors such as hemangiomas [40, 41].

10.3.2 Absolute Contraindications

- Asymptomatic vertebral body tumors without fracture
- Cord compression
- Osteomyelitis, discitis, or active systemic infection
- Uncorrectable coagulopathy

10.3.3 Relative Contraindications

- Fracture of the posterior vertebral body wall—increased risk of cement leak and bone fragment displacement.

10.3.4 Procedure

- The procedure is performed under local anesthesia as an outpatient procedure.
- The patient is positioned prone for the lumbar and thoracic levels and supine for the cervical level.
- The classic transpedicular route is employed for the lumbar and thoracic levels. In the cervical vertebrae, an anterolateral approach is used.
- After the placement of bone biopsy needle(s) in the anterior one-third of the vertebral body, radio-opaque vertebroplasty cement is injected under continuous fluoroscopic monitoring.

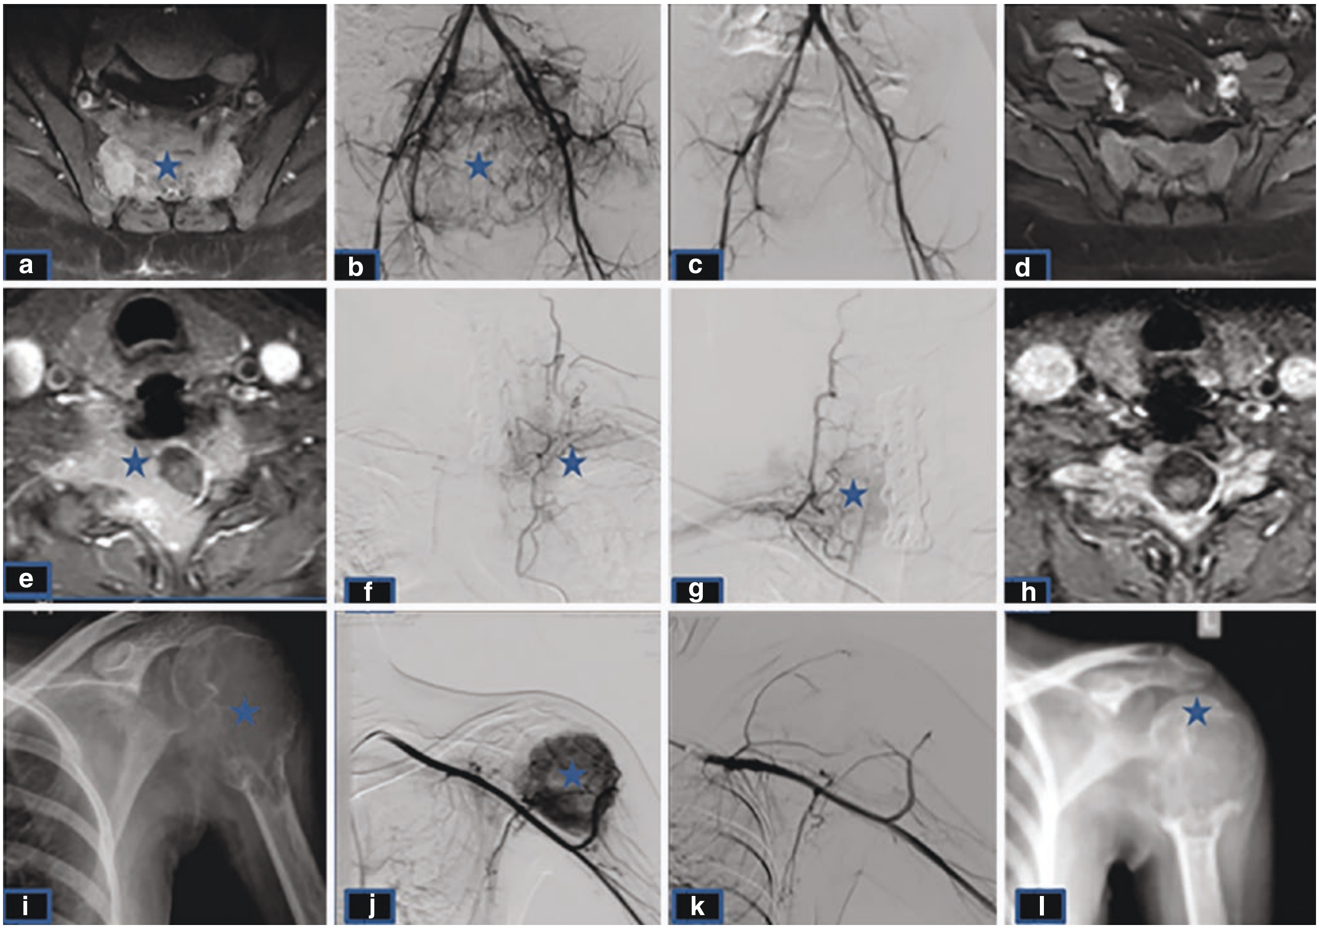

Fig. 15 Angioembolization as definitive treatment for sacral GCT (**a**–**d**), cervical GCT (**e**–**h**), and humeral GCT (**i**–**l**)

10.3.5 Complications

- Cement leakage (epidural space, perivertebral venous plexus, disc space, and paravertebral tissue) is the most frequent complication and is usually asymptomatic.
- Infection occurs in less than 1%.
- Bleeding.

10.4 Angioembolization of Bone Tumors

10.4.1 Indications

- Serial angioembolization with or without denosumab to achieve local control in Sacral giant cell tumors (GCT) or in cases of proximal femoral or humeral GCT where torniquet cannot be tied (Fig. 15).
- Preoperative embolization to reduce intra-operative blood loss and also surgical time—primary osseous tumors included GCT, aneurysmal bone cyst (ABC), osteoblastoma, chondroblastoma, and chondrosarcoma.
- Pain palliation for bone metastases [42–44].

10.5 Ophthalmic Artery Chemoinfusion for Retinoblastoma

Retinoblastoma is the most common eye tumor in children, leading to death within 1–2 years if left untreated. The tools for the management of retinoblastoma include surgery (enucleation), radiation therapy, systemic chemotherapy, and focal therapies (including cryotherapy, laser photocoagulation, and transpupillary thermotherapy). Intra-arterial chemotherapy (ophthalmic artery chemoinfusion) has emerged as one of the effective options for local disease control and has been found very effective as a globe-conserving strategy [45].

The intra-arterial chemotherapy is done under general anesthesia. The technique involves navigating through the internal carotid artery to selectively enter the ophthalmic artery (OA), followed by injection of the chemotherapy drugs specifically into the artery leading to the tumor (Fig. 16d).

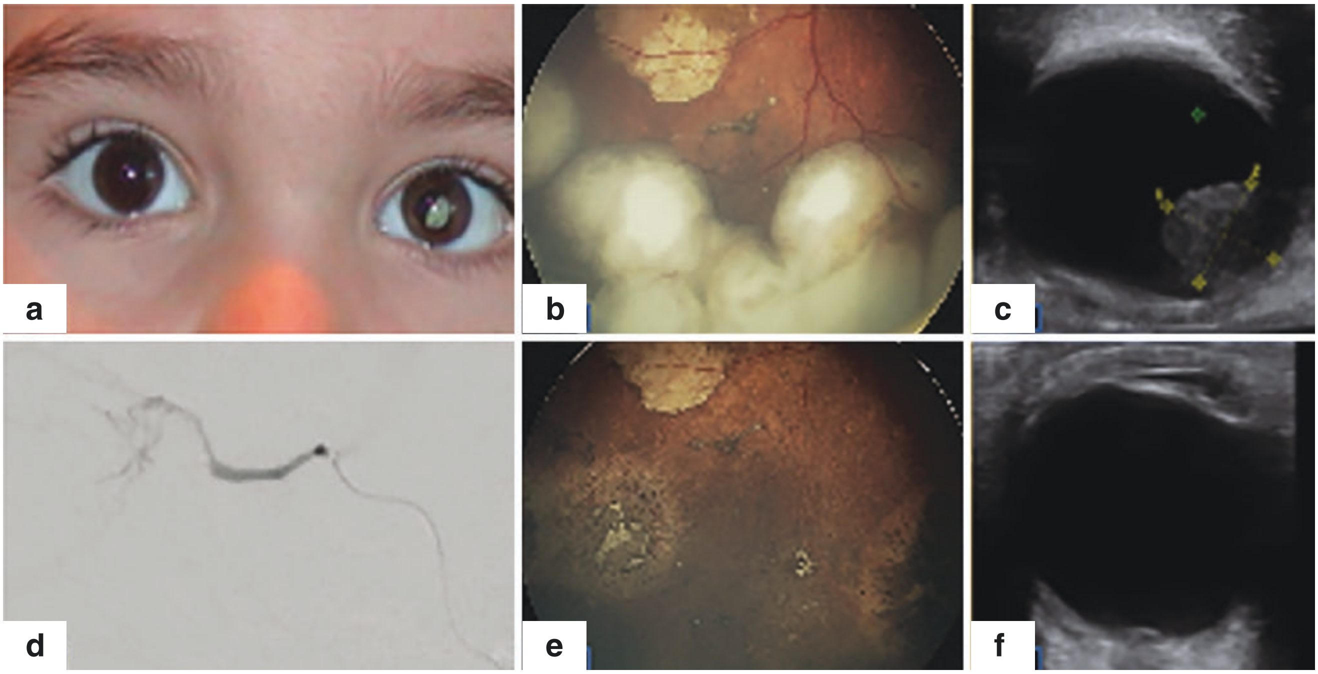

Fig. 16 (**a**) White reflex in a c/o retinoblastoma. (**b**) Ophthalmological examination. (**c**) B scan showing a lesion in the posterior chamber. (**d**) Ophthalmic artery chemoinfusion. (**e**) Follow-up ophthalmological examination. (**f**) Follow-up B scan

The number of sessions for such treatment is 1–5, with most children requiring an average of 2–3 sessions. The child undergoes an eye examination by an ophthalmologist (Fig. 16b, e) and a B scan (Fig. 16c, f) after each session to assess the tumor response to treatment.

The advantages of ophthalmic artery chemoinfusion are as follows:

- Maximum delivery of the chemotherapeutic drug to the tumor and minimum toxicity to other organs of the body.
- Globe can be salvaged in group D disease in 75–84% of cases [46].
- Downstaging to definitive targeted focal therapy like laser therapy.
- OAC can be combined with systemic chemotherapy to salvage the eye in group E disease [47].

10.6 Lymphangiography and Thoracic Duct Embolization

10.6.1 Indications

- Injury to the thoracic duct occurs commonly during thoracic or neck surgeries (up to 3% of esophagectomies), resulting in chylous pleural or pericardial effusion.
- Chylous ascites may develop after surgery involving extensive thoracoabdominal, retroperitoneal, or pelvic nodal dissection.

In patients with leaks persistent with conservative management, intervention is performed. The options include surgical ligation and percutaneous thoracic duct embolization. Percutaneous embolization of the thoracic duct has an approximately 80% success rate in controlling chylous leaks due to thoracic duct injury.

10.6.2 Procedure

- Lymphangiography can be done by injecting lipiodol into the inguinal lymph nodes under ultrasound guidance (instead of the traditional technique of cannulating the lymphatic channel in the dorsum of the foot after injecting methylene blue in the first web space for identification). The flow of lipiodol is visualized with intermittent fluoroscopy (Fig. 17a).
- The thoracic duct can be accessed after its opacification by percutaneous transabdominal puncture under fluoroscopic guidance.
- Alternatively, it can also be catheterized via the transvenous route where it enters the left subclavian vein (Fig. 17b, c).
- When access to the thoracic duct is gained, a microcatheter is advanced, and embolization is performed with multiple coils and *N*-butyl cyanoacrylate (n-BCA) glue (Fig. 17d).
- If the access to cisterna chyli fails, thoracic duct disruption can be achieved by puncturing the cisterna chyli multiple times.

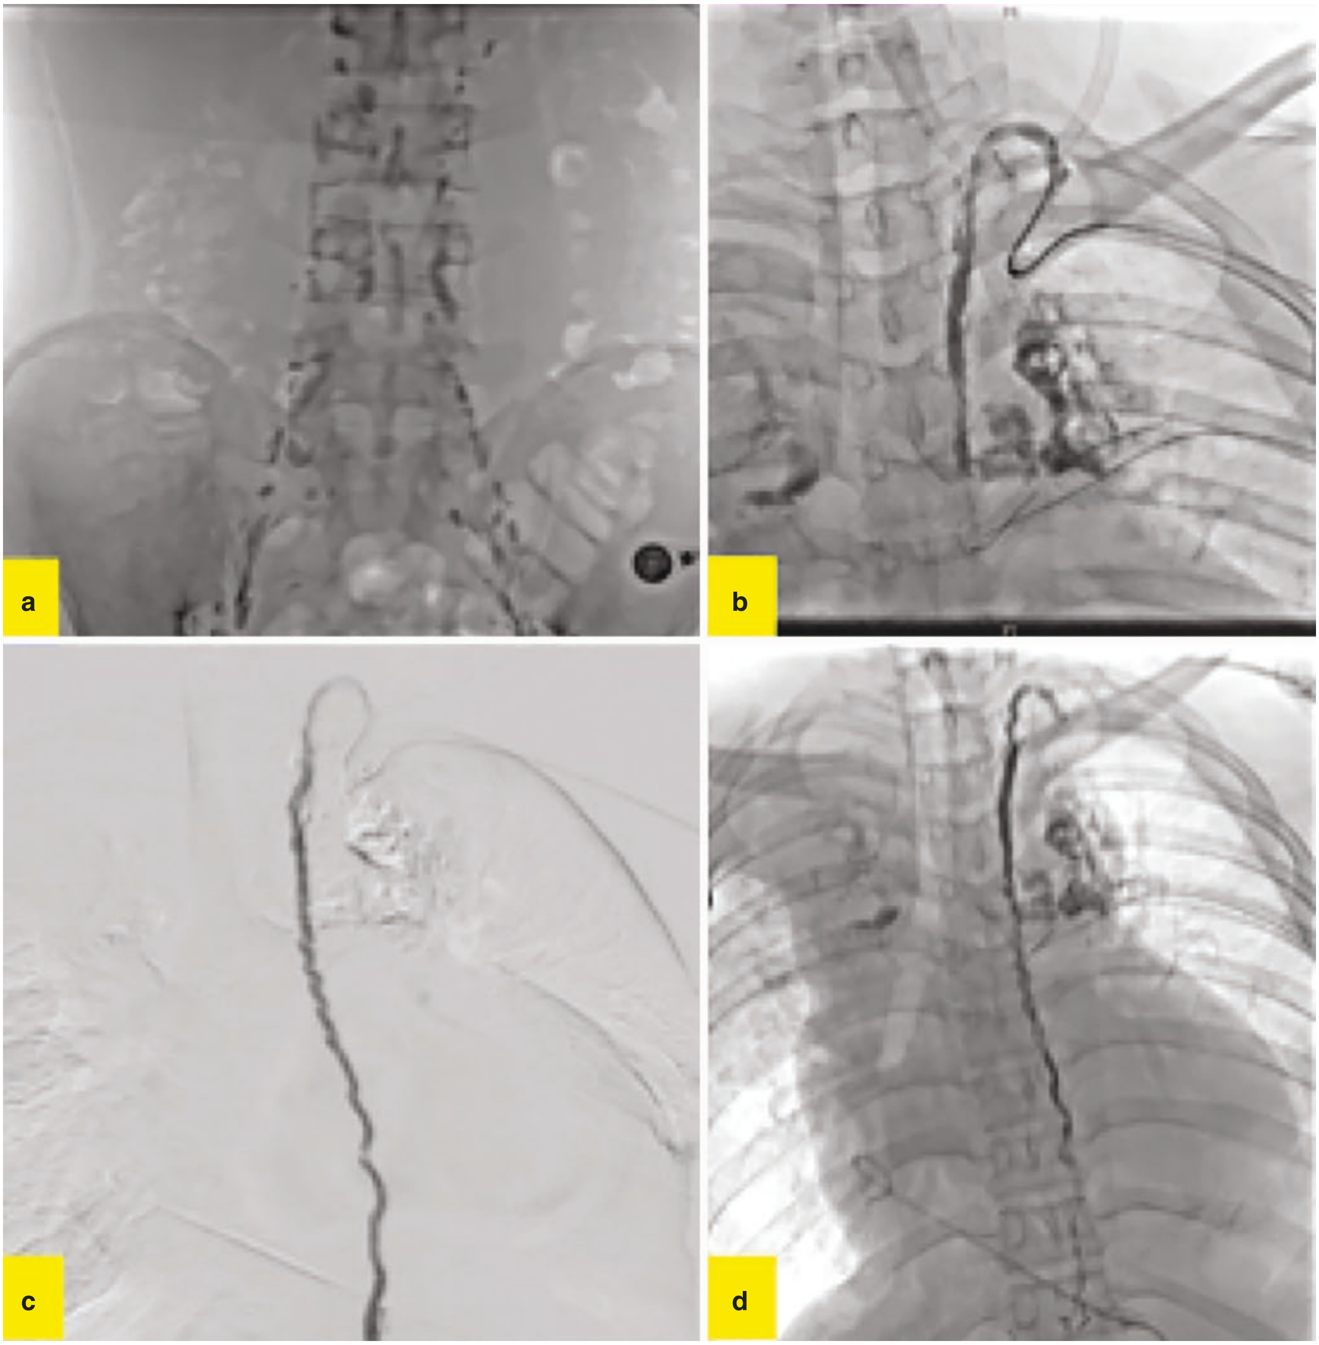

Fig. 17 (**a**) Lymphangiogram after injecting lipiodol into inguinal LN. (**b**) Transvenous cannulation of the thoracic duct. (**c**) Thoracic duct angiogram. (**d**) Post glue embolization of thoracic duct

11 Emergencies

Situations in which urgent or emergency interventional radiology is indicated are presented in Fig. 18.

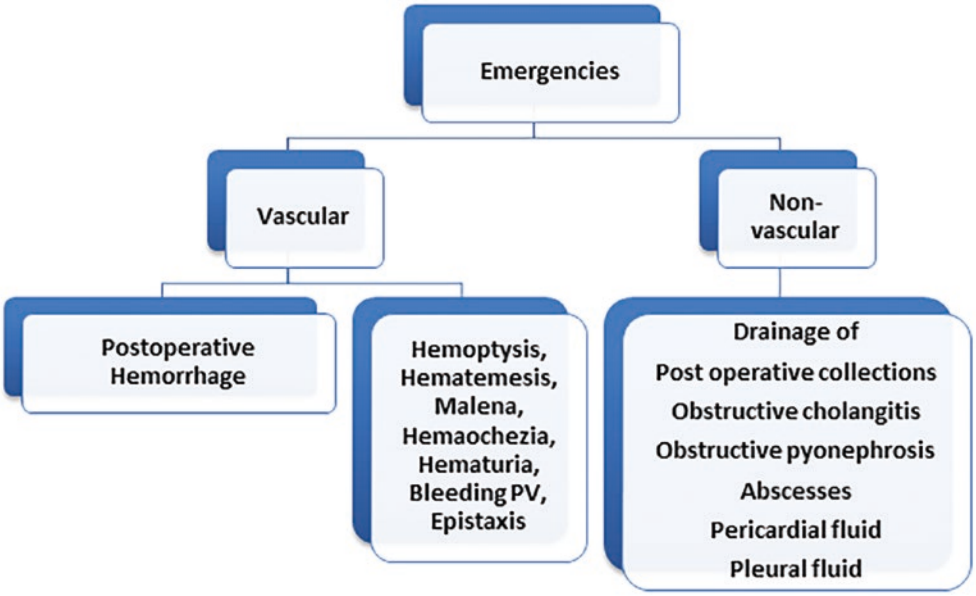
11.1 Vascular Intervention

Arterial intervention: Embolization of hemorrhage, especially postoperative bleeding, tumoral bleeding (hypervascular tumors, infiltration of vessels), bleeding from the gastrointestinal tract, urinary tract, airways, and head and neck.

Venous intervention: Insertion of IVC filter, mechanical pulmonary thrombectomy.

11.2 Gastrointestinal Bleeding

GI bleeding is conventionally categorized by the anatomical location of the bleeding source (Table 4). A gastrointestinal (GI) bleeding source proximal to the ligament of Treitz,



Emergencies
Vascular
Non-vascular
Postoperative Hemorrhage
Hemoptysis, Hematemesis, Malena, Hemaochezia, Hematuria, Bleeding PV, Epistaxis
Drainage of
Post operative collections
Obstructive cholangitis
Obstructive pyonephrosis
Abscesses
Pericardial fluid
Pleural fluid

Fig. 18 Situations in which urgent or emergency interventional radiology is indicated

Table 4 Gastrointestinal bleeding

Features	Upper GI bleed	Lower GI bleed
Site	Above ligament of Trietz	Below ligament of Trietz
Presentation	Hematemesis or melena	Hematochezia
Nasogastric aspiration	Blood	Clear fluid
BUN/creatinine ratio	Increased	Normal
Bowel sounds	Hyperactive	Normal

which occurs more frequently, is classified as part of upper GI, and a source distal to the ligament of Treitz is considered part of lower GI [48–50].

11.2.1 Causes of Upper GI Bleeding

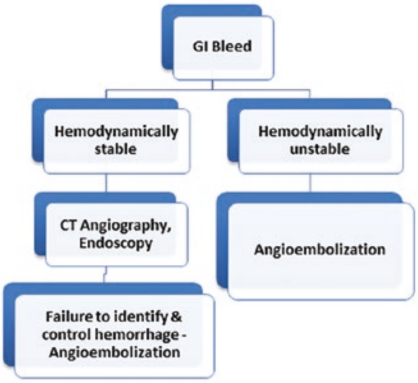
Malignancy (vascular tumors, ulcerative lesions, tumors that are infiltrating into blood vessels), peptic ulcer, varices, gastritis, and duodenitis.

11.2.2 Causes of Lower GI Bleeding

Colorectal carcinoma or other pelvic tumors infiltrating the rectum or colon, inflammatory bowel disease, and diverticulosis.

11.2.3 Evaluation of the Patient with Bleed (Fig. 19)

- History: hematemesis, melena, hematochezia, and anticoagulants.
- Examination: vitals, signs of chronic liver disease.
- If hemodynamically unstable—resuscitate with IV fluids and blood products.



GI Bleed
Hemodynamically stable
Hemodynamically unstable
CT Angiography, Endoscopy
Angioembolization
Failure to identify & control hemorrhage - Angioembolization

Fig. 19 Approach to a patient presenting with gastrointestinal hemorrhage

- Laboratory tests: hemoglobin, platelets, coagulation profile, LFT, and RFT.

Angioembolization

- Angiography can identify an active bleeding rate of at least 0.5–1 mL/min.
- Femoral access is taken, and a mesenteric angiogram is performed.
- Superselective angiograms of the suspected vessels as guided by clinical details and prior imaging is done, and this is followed by embolization of the abnormal vessels identified to be the cause of bleeding (Fig. 20a–d).
- Augmentation maneuvers:
  - Selective intra-arterial injection of nimodipine, papaverine, and heparin.
  - Withholding of vasopressor supports for some time to unmask bleeding vessel.

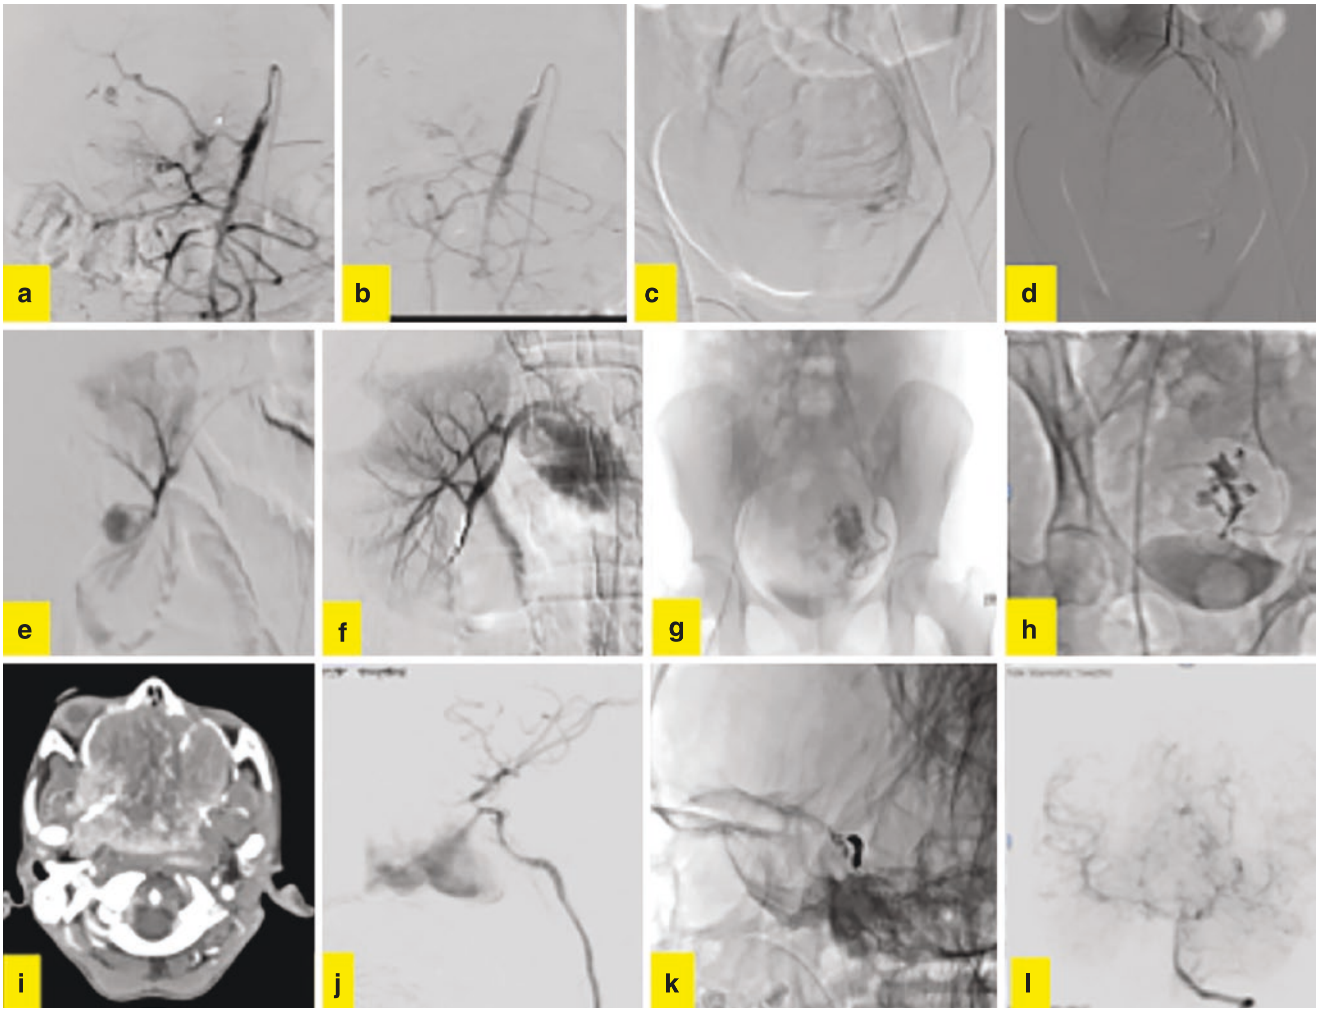


Fig. 20 (**a**) Postoperative hematemesis, SMA angiogram showing pseudoaneurysm. (**b**) SMA angiogram post glue embolization. (**c**) C/o hematochezia, left superior rectal artery angiogram showing pseudoaneurysm. (**d**) Post-embolization angiogram. (**e**) C/o post-PCN hematuria, right renal artery angiogram showing pseudoaneurysm. (**f**) Post coil embolization angiogram. (**g**) Bleeding PV in a c/o invasive mole, left uterine artery angiogram. (**h**) Glue embolization. (**i**) CECT in c/o JNA. (**j**) Postoperative right ICA blowout. (**k**) Coil embolization. (**l**) Contralateral angiogram showing support from contralateral arteries

Positive Findings

- Extravasation of contrast agent is indicative of active bleeding.
- Mucosal blushes with abnormal vessels suggestive of a tumor.
- Prolonged contrast spots suggestive of inflammation.
- Visualization of nidus with early draining vein suggestive of an AV malformation.
- Other lesions—pseudoaneurysms and AV fistulas [51, 52].

11.2.4 Complications

- Nontarget embolization.
- Bowel ischemia: avoid nontarget embolization to prevent bowel ischemia. The patient has to be monitored post-procedure clinically and with serum lactates for bowel ischemia, which would require surgery and resection of the ischemic segment of the bowel.
- An arterial injury such as dissection, perforation, pseudoaneurysm, and vasospasm [53].

11.3 Hemoptysis and Bronchial Artery Embolization

Hemoptysis is defined as the coughing up of blood originating from the lower respiratory tract. Patients with massive hemoptysis (>300 mL in 24 h) have high mortality primarily due to the risk of aspiration and asphyxiation.

Oncologic causes of hemoptysis include primary or metastatic pulmonary malignancy or infections due to post chemotherapy-related infection. Other causes of hemoptysis include tuberculosis, fungal infections, abscess, bronchiectasis, pneumonia, and chronic bronchitis. Ninety percent of cases of massive hemoptysis requiring intervention originate from the bronchial arteries [54].

11.3.1 Pre-procedural Imaging and Endovascular Treatment

CT angiography is the diagnostic modality of choice for assessing and characterizing hemoptysis. It identifies the cause of the bleed, localizes the site, and provides a vascular road map for endovascular intervention. Hypertrophy of the bronchial artery (diameter >3 mm), in conjunction with other imaging findings, improves the sensitivity and specificity of localization of the bleeding source [55, 56]. The target artery is selectively cannulated and embolized using particles.

11.3.2 Outcomes

Technical success is more than 90%, while clinical success ranges from 73% to 94%. Recurrence rates are high if the underlying disease (example: tuberculosis, bronchiectasis) is left untreated.

11.3.3 Complications

Post-embolization syndrome resulting in pleuritic pain, fever, dysphagia, and leukocytosis can occasionally occur and last for 5–7 days. Paraplegia, an unusual and the most dreaded complication of bronchial artery embolization, occurs when the spinal artery arising from the bronchial artery is not identified, resulting in inadvertent embolization of this artery.

11.3.4 Management of Hematuria and Bleeding per Vaginum

The basic patient preparation, intra-procedural care, and angiographic techniques are the same as described above. For hematuria, renal and bilateral internal iliac artery angiograms are taken depending on whether the source of bleeding is kidney or bladder/prostate. For bleeding PV, bilateral internal iliac artery and selective uterine/cervical artery cannulation are performed. Endovascular treatment should always be considered as the first option to control bleeding over hysterectomy. Embolization is performed after super selectively cannulating the culprit artery (Fig. 21e–h).

11.3.5 Management of Postoperative Hemorrhage

Postoperative bleeding is sometimes encountered due to pseudoaneurysms at the site of the ligated vessel, pseudoaneurysm formation due to postoperative inflammation/infection, and slippage of ligature from vessels. It is challenging to re-explore the patient for bleeding as postoperative changes and adhesions make it difficult to identify the bleeding source and add to the morbidity of a second open surgery. Digital subtraction angiography plays a vital role in such patients by identifying the abnormal bleeding sources and embolization of the same (Fig. 20a, b, i–l).

11.3.6 Management of Deep Venous Thrombosis and Pulmonary Thromboembolism

Acute deep venous thrombosis (DVT) is rising and particularly high in postoperative and cancer patients. Anticoagulation is the mainstay of DVT therapy to prevent DVT progression and pulmonary thromboembolism (PE) [57, 58].

Indications for catheter-directed thrombolysis for DVT [59, 60]:

- Acute limb-threatening circulatory compromise.
- Extensive IVC thrombosis (high risk of fatal PE).
- Acute renal failure from thrombus extension into renal veins.
- Clinical or anatomic progression of DVT while on anticoagulant therapy.

Indications for catheter-directed thrombolysis/thromboaspiration for PE:

- Acute massive PE presenting with shock, hypotension (SBP <90 mmHg), or other signs of systemic hypoperfusion.
- Patients with submassive PE with right ventricular dysfunction (RV strain on 2D Echo, raised cardiac enzymes, RV: LV ratio > 1).

Contraindications for catheter-directed thrombolysis:

- Active bleeding
- Recent (<10 days) major surgery, trauma, CPR
- Severe liver dysfunction
- Recent intracranial hemorrhage (<6 months)
- Bacterial endocarditis
- Intracranial tumor

Such patients can safely undergo mechanical thrombectomy/thromboaspiration.

11.3.7 Procedure

Femoral (preferably) or jugular venous access is taken. The catheter guidewire combination is advanced into the main pulmonary artery, and a long sheath is placed over the stiff wire. An angiogram is taken. The aspiration catheter is subsequently navigated to the site of thrombus in the pulmonary arteries, followed by suctioning via tubing attached to the suction pump. Serial angiograms are performed to look for residual thrombus and guide further thromboaspiration

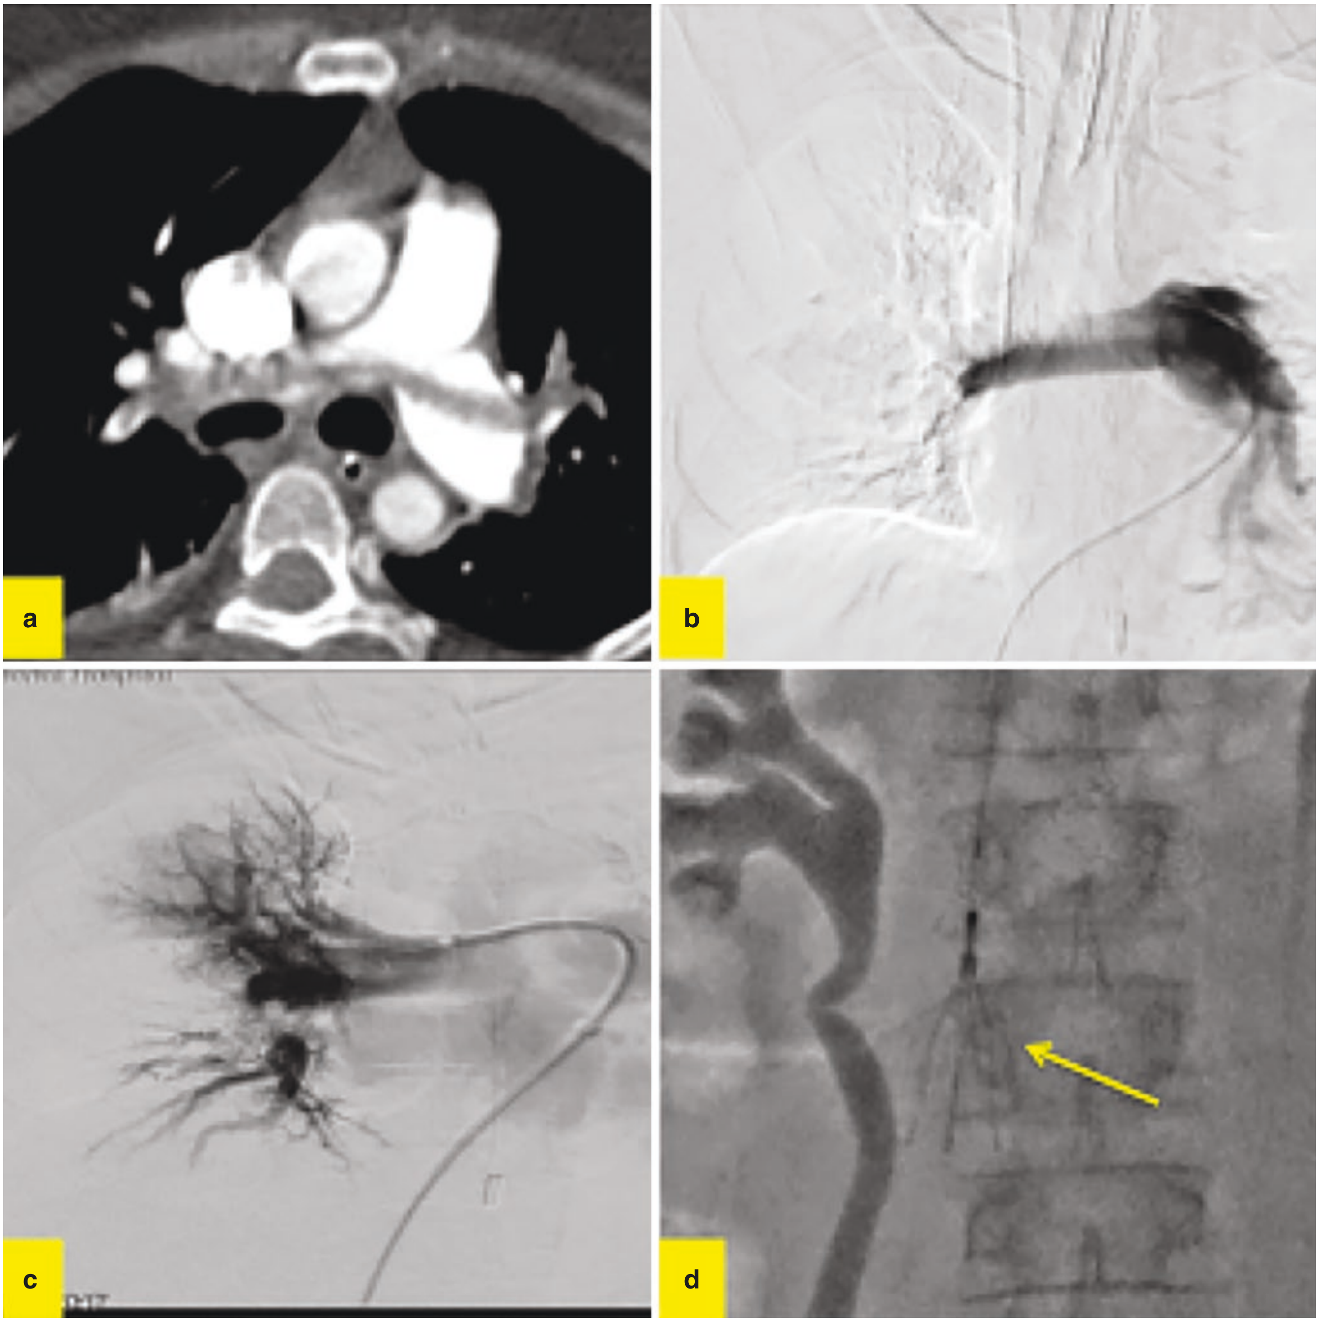

Fig. 21 (**a**) Pulmonary thromboembolism in a c/o DVT. (**b**) MPA angiogram. (**c**) MPA angiogram post thromboaspiration. (**d**) IVC filter

(Fig. 21a–c). Thrombolysis is done with urokinase or r-TPA after calculating the dose per the patient's weight and ruling out any contraindications.

A filter device (Fig. 21d) is deployed in the IVC after pulmonary thromboaspiration in patients with residual DVT to prevent further PE. The filter can be temporary (retrievable) or permanent depending on the intent of treatment and expected survival of the patient, with permanent filters being preferred in patients with the palliative intent of therapy.

1 Introduction

The World Health Organisation (WHO) reports cancer as the second leading cause of death globally and was responsible for 8.8 million deaths in 2015. Approximately 70% of deaths from cancer occur in low- and middle-income countries (www.who.int/en/news-room/fact-sheets/detail/cancer). About 60–80% of these patients may need surgery for various indications ranging from diagnostic, therapeutic or palliative procedures. Most of the top ten cancers in India responsible for disability in 2016 [stomach (9.0% of the total cancer disability-adjusted Life years), breast (8.2%), lung (7.5%), lip and oral cavity (7.2%), pharynx other than nasopharynx (6.8%), colon and rectum (5.8%), leukaemia (5.2%), cervical (5.2%), oesophageal (4.3%) and brain and nervous system (3.5%)] require surgical treatment [1].

Neo-adjuvant chemotherapy is widely practiced for several cancers, and cancer patients may have undergone received chemotherapy (including newer agents for targeted therapy) and/or radiotherapy with implications for anaesthetic management. Surgical advances have resulted in both highly complex and invasive procedures (e.g. cytoreductive surgery, hyperthermic intraperitoneal chemotherapy) as well as minimally invasive procedures (e.g., robotic surgery) gaining popularity. Patients are often elderly, with several comorbidities. Perioperative management of these patients should focus on safe anaesthesia as well as optimising postoperative surgical outcomes. Oncoanaesthesia refers to the practice and study of

anaesthetic techniques and perioperative interventions that can help facilitate early return to intended oncological treatment and potentially minimise cancer recurrence and improve oncological outcomes. This chapter will provide a brief overview of the perioperative care of cancer patients.

2 Preoperative Chemotherapy

Chemotherapeutic drugs effects can range from mild to severe adverse effects. Most of these drugs affect the gastrointestinal and haemopoieitic system. Gastrointestinal toxicity results in nausea and vomiting, mucositis and diarrhea and electrolyte disturbances. If urgent/emergency surgery is indicated in patients undergoing chemotherapy with GI manifestations, then fluid balance and electrolytes should be optimised before surgery. Care should be taken during laryngoscopy as trauma can exacerbate the mucositis and cause severe bleeding leading to difficult visualisation of the airway.

Myelosuppression is usually partially or completely reversible within 6 weeks of cessation of chemotherapy. Long duration of neutropenia was identified as one of the predictors of overall survival in these patients; therefore, surgery should be delayed, when possible, to allow for neutrophil recovery. Preoperative administration of granulocyte colony-stimulating factors (GCSF) may be considered in these cases to expedite reaching this threshold. It is prudent to order a complete blood count before elective surgery [2, 3]. Elective surgery is planned after recovery of myelosuppression. Incidental surgery may be needed for neutropenic enterocolitis, small bowel obstruction and perforative peritonitis before recovery of myelosupppression. In these cases, there can be increased risk of bleeding and opportunistic infection if the platelet count is low (<50,000/cmm) and absolute neutrophil count is less than 1000/cmm, respectively.

Certain drugs affecting various organ-specific toxicities and the clinical implications are outlined in Table 1.

Table 1 Chemotherapeutic agents, organ toxicity, mechanism of action, presentation and clinical implication for preoperative assessment and evaluation

Organ involved	Drug	Mechanism of organ toxicity	Clinical manifestation	Clinical implication
Cardiovascular	Anthracyclines [4] • Doxorubicin • Daunomycin • Idarubicin • Epirubicin Cisplatin Pentotastin Ifosfamide Cladiribine Mitoxantrone	Permanent structural changes (Type 1) in the cardiac myocyte, which worsen with repeated doses, i.e. cumulative effect.	Cardiac toxicity may be life threatening or with significant morbidities. They can be immediate or delayed after completion of the course of chemotherapy. They can range from hypotension, hypertension, arrhythmias, myocardial infarction, congestive cardiac failure, cardiomyopathy, myocarditis, and pericarditis, leading to pericardial effusion and cardiac tamponade.	• Focused history and examination, for signs and symptoms of cardiac dysfunction should be elicited. • Electrocardiogram and 2D echocardiogram (Echo) should be requested. Echo should focus on myocardial contractility, left ventricular ejection fraction, and pericardial fluid. • Asymptomatic patients with minimal or no echocardiographic changes indicative of cardiomyopathy may show subclinical cardiac dysfunction, which is only seen as a diminished ability to exercise. • For agents with cumulative effect, Echo is required before surgical procedure even years after chemotherapy. • Cardiology referral may be needed for preoperative optimisation. • Intravenous induction agents have an exaggerated myocardial depressant effect even in patients with apparently normal cardiac function. Dose titration to clinical effect is prudent. • Invasive arterial pressure and cardiac output monitoring may be needed depending on the cardiac morbidity and surgical procedure.
	Tyrosine kinase inhibitors— • Sunitinib • Imatinib • Sorafenib • Lapatinib • Dasatinib Monoclonal antibody • Trastuzumab • Bevacizumab	Type 2 changes in cardiac myocyte, which are reversible despite repeated doses.	Cause hypertension and congestive heart failure, which may be associated with elevated troponin levels. Bevacizumab can also cause severe thromboembolic events.	
	Cyclophosphamide	Direct endothelial damage.	Haemorrhagic pericarditis or myocarditis. Incidence of cardiotoxicity is lower in children than in adults, due to an age-related resistance as well as the lower doses administered to children.	

Table 1 (continued)

Organ involved	Drug	Mechanism of organ toxicity	Clinical manifestation	Clinical implication
Renal	Platinum-based [5] • Cisplatin • Carboplatin • Oxaliplatin	Renal tubular and glomerular damage.	They can cause either acute or chronic renal failure.	• Nephrotoxicity is compounded by dehydration and concurrent use of non-steroidal anti-inflammatory drugs. • Careful fluid optimisation and analgesic use during the perioperative period.
	Ifosfamide	Proximal tubular abnormality.		
	Cyclophosphamide	Haemorrhagic cystitis.		
	Mitomycin C	Syndrome encompassing microangiopathic haemolytic anaemia and renal failure.		
Respiratory	Bleomycin [6]	6–10% incidence of pulmonary toxicity. Oxidative damage, Relative deficiency of deactivating enzyme bleomycin hydroxylase, genetic susceptibility and presence of inflammatory cytokines are predisposing factors. High inspired oxygen concentrations can cause rapid progression of pulmonary toxicity.	Can be fatal. Diagnosis of bleomycin induced lung injury is established by a combination of clinical presentation, respiratory function abnormalities, radiological and histological features. Common symptoms are exertional dyspnoea and non-productive cough, which can progress to dyspnoea at rest, tachypnoea and cyanosis. Can occur during treatment or within first 6 months of treatment.	• Investigations required may include a CXR, ABG, CT chest PFT and DLCO. • Lowest FiO$_2$ should be administered to achieve a target range of SpO$_2$ between 88% and 92%. • If oxygen saturations are higher than this, then oxygen should be stopped or the dose reduced. Protective lung ventilator strategy using PEEP and careful fluid balance. • Postoperatively, chest physiotherapy, good analgesic regimes, and early mobilisation. Pulmonary toxicity is a lifelong risk in these patients so exposure to high concentrations of O$_2$ should be limited.
Nervous system	Vincristine [3]	Inhibits microtubule formation and DNA/RNA synthesis.	Peripheral neuropathy, muscle pain, cranial neuropathy, autonomic neuropathy, and in severe cases seizures. Autonomic neuropathy is a major concern for anaesthetists. Neurotoxicity is usually reversible on interruption of the therapy, but the recovery is slow and takes several months.	• Regional anaesthesia is relatively contraindicated in any patient demonstrating neurological side-effects after chemotherapy treatment and if essential it should be attempted after thorough neurological examination and documentation of deficit.
	Cisplatin Paclitaxel Oxaliplatin	Causes DNA damage-induced apoptosis of dorsal root ganglion neurons.	Most commonly presents as distal dose-dependent symmetrical sensory neuropathy.	
	High-dose methotrexate [7]	Possibly disruption of central nervous system folate homeostasis and/or direct neuronal damage.	Present with transient stroke-like symptoms, encephalopathy, seizures (usually reversible).	
	Ifosfamide [8]	Not known.	Causes metabolic encephalopathy of varying severity. Neurotoxicity is self-limiting and reversible between 48 and 72 h after discontinuation of ifosfamide.	

CXR chest X-ray, *ABG* arterial blood gas, *CT* computerized tomography, *PFT* pulmonary function test, *DLCO* diffusing capacity for carbon monoxide, FiO_2 fraction of inspired oxygen concentration

3 Preoperative Radiotherapy

Radiotherapy is frequently used in combination with chemotherapy for oesophageal, pulmonary, cervical, head and neck, rectal and urinary bladder cancers. Radiotherapy causes tissue damage along its path via production of oxygen-free radicals. Superficial tissues are maximally affected compared to deeper tissues. Side effects depend on the area affected. It causes delayed wound healing, induration of the skin, vascular stenosis, myocarditis, pneumonitis and pulmonary fibrosis. Head and neck cancers present as challenge to the anaesthetists, especially in airway management. Induration of the tissues may result in limited neck extension, restricted mouth opening, tongue mobility and rigidity and oedema of the oropharyngeal tissues. This may make facemask ventilation and laryngoscopy difficult. The anaesthetist has to be prepared with airway management plan and extubation strategy.

4 Perioperative Care

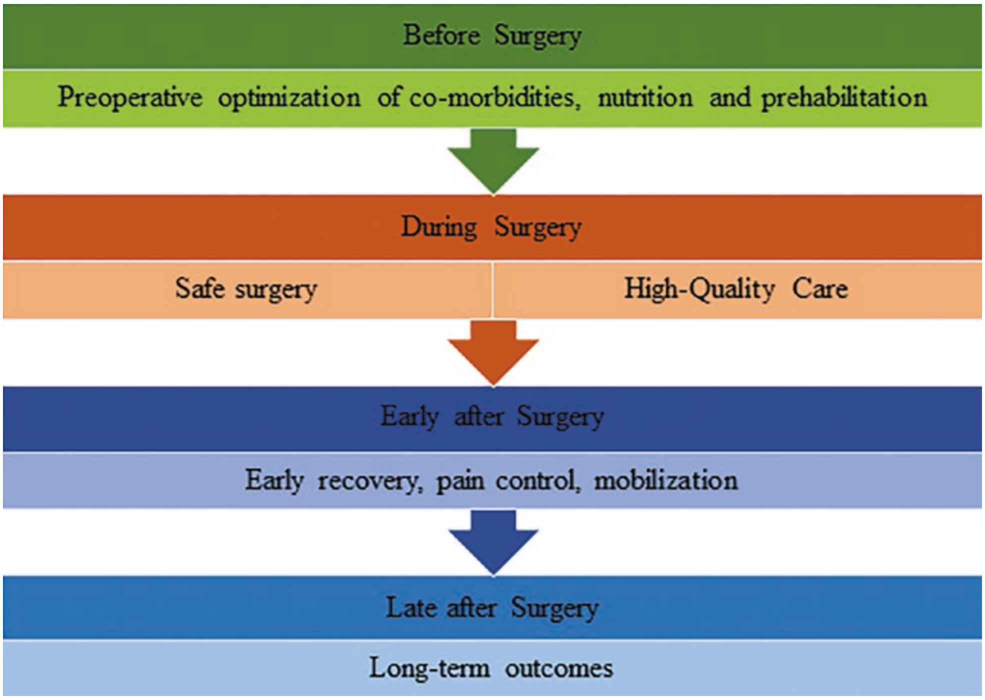
Perioperative care is a continuum of care, starting from the preoperative evaluation, intraoperative management and postoperative care (Fig. 1). Optimal perioperative care is essential for good short-term outcomes as well as long-term outcomes.

The aim of the preoperative evaluation is to identify the high-risk patient (Table 2) and to optimise pre-existing medical conditions. Appropriate specialist referral and consultation should take place on an individualised basis.

Several corrective problems must be identified and treated. These include malnutrition, anaemia, ischaemic heart disease (IHD), diabetes mellitus, pulmonary disease and optimisation of fluid volume to reduce the incidence renal dysfunction.

Table 2 Identifying the high-risk patient for cancer surgery

Patient factors	Surgical factors
• Prior severe cardiac illness (acute myocardial infarction, stroke, congestive heart failure) • Age >70 years, limited physiologic reserve of ≥1 organs • Sepsis and with septic shock • Severe nutritional problems • Respiratory distress, chronic obstructive pulmonary disease, patient requiring mechanical ventilation • Hepatic or renal dysfunction	• Extensive ablative surgery for cancer, >8 h • Massive blood loss >8 units • Vascular surgery • Acute abdominal catastrophe-peritonitis, perforated bowel with gangrene



Before Surgery
Preoperative optimization of co-morbidities, nutrition and prehabilitation
During Surgery
Safe surgery
High-Quality Care
Early after Surgery
Early recovery, pain control, mobilization
Late after Surgery
Long-term outcomes

5 Cardiovascular Evaluation in Patients Undergoing Oncologic Surgery

With improved access to healthcare, there is growing population of elderly with multiple comorbidities, especially IHD. Cardiovascular evaluation is an important aspect of pre-anaesthetic assessment. Most oncologic surgical procedures are classified as time sensitive, i.e. a delay of >1–6 weeks can be allowed for evaluation and significant changes in management will negatively affect outcome. Prior cardiac events such as recent myocardial infarction (MI) are often associated with major adverse cardiac events (MACE); their timing and stability have an impact on the perioperative morbidity and mortality. As the duration between onset of MI and timing of surgery increases the incidence of postoperative MI and mortality decreases from 32% and 14% within 1 month to 5.9% and 10% at 6 months after MI, respectively [9]. According to the American College of Cardiology (ACC)/American Heart Association (AHA)/guidelines at least 2 months should elapse after MI before non-cardiac surgery in the absence of a coronary intervention. In addition to cardiac morbidity and mortality, recent MI (within 6 months of non-cardiac surgery) is associated with increased risk of perioperative stroke and an eightfold increase in mortality [10]. Patients having three or more of the following risk factors have a >10% chance of suffering a MACE: high-risk surgical procedure (intrathoracic, intraperitoneal or supra-inguinal vascular reconstruction); history of IHD (excluding revascularisation); history of congestive cardiac failure; history of stroke or transient ischaemic attack; insulin-dependent diabetes mellitus; preoperative insulin therapy (diabetes) and creatinine >2.0 mg% [11].

The ACC/AHA recommendations for preoperative evaluation of patients with IHD are summarised in Fig. 2.

Cardiopulmonary exercise test (CPET) is a non-invasive procedure that involves the measurement of expired ventilation, oxygen (O_2) consumption and carbon dioxide (CO_2) production during incremental exercise. It may be superior to standard ECG stress testing in detecting both overt and occult exercise-induced myocardial ischaemia. Maximal increase in O_2 consumption (VO_2) with exercise (peak VO_2) < 15 mL/kg and anaerobic threshold <10 mL O_2/kg/min are associated with poor postoperative outcome.

Revascularisation (coronary artery bypass graft surgery or percutaneous coronary intervention [PCI]) is not recommended before non-cardiac surgery exclusively to reduce perioperative cardiac events. Indication for revascularisation depends on severity of IHD, rather than impending surgery. In patients who have had PCI, the immediate period after a PCI is a high-risk period because of the rupture of its endothelial covering. Non-cardiac surgery is risky till epithelialisation, with a high rate of AMI (up to 30%) and mortality (20–40%). Dual antiplatelet therapy (DAPT) with aspirin and $P2Y_{12}$ platelet receptor–inhibitor (e.g., clopidogrel) is mandatory to prevent in-stent thrombosis. Discontinuation of DAPT following PCI is one of the strongest predictors of stent thrombosis. The risk of stent thrombosis and mortality is inversely proportional to the timing of surgical procedure. The new generation drug eluting stents (DES) are associated with a lower risk of stent thrombosis and require a shorter minimum duration of DAPT. Current recommendation for discontinuation DAPT before elective non-cardiac surgery for bare metal stent (BMS) is >30 days after implantation and 3–6 months for DES (if the risk of delaying surgery is greater than risk of stent thrombosis). Safe duration for discontinuation of DAPT for DES is 6 months after implantation [12]. Continuation of DAPT is associated with increased bleeding risk during surgery. The decision to continue or withhold DAPT should be individualised depending on the urgency of non-cardiac surgery. If decision to discontinue clopidogrel is taken, then aspirin should be continued perioperatively and $P2Y_{12}$ platelet receptor–inhibitor should be restarted as soon as possible after surgery [13].

6 Frailty and Anaesthesia

Elderly patients undergoing surgical procedures are more vulnerable to adverse postoperative outcomes compared to younger patients. Functional status, gait and mobility and frailty are important determinants of outcome [14]. Frailty is a state of reduced physiological reserve as a result of long-term illness, multiple comorbidities leading to progressive decline in physical and cognitive function. These patients will have loss of muscle mass, reduced strength and endurance. Frailty is associated with worse postoperative

Table 3 Screening for frailty [15]

Criteria	Definition
Shrinkage	Unintentional weight loss ≥10 lb over the past year
Weakness	Decreased grip strength
Exhaustion	Self-reported poor energy and endurance
Low physical activity	Low weekly energy expenditure
Slowness	Slow walking

1 point for each criterion met
0–1: Not frail; 2–3: Intermediate frail (pre-frail); 4–5: Frail

outcomes such as increased postoperative complications, prolonged stay and mortality. Elderly patients are more prone to postoperative delirium and postoperative cognitive dysfunction.

Preoperative interventions such as prehabilitation can be initiated to improve muscle strength, mass and thus physical function [15]. Similarly, improving nutrition, physiotherapy, screening for cognitive disorder, treatment of depression or mood disorders if any. During anaesthesia, in addition to other aspects of anaesthetic care particular attention is needed to maintain normothermia, avoidance of fluid overload, titrate depth of anaesthesia to avoid deep levels of anaesthesia, as it is associated postoperative delirium and cognitive decline. Lastly, frailty should be assessed and incorporated in to decision-making process taking in to consideration its association with worse postoperative outcomes (Table 3).

7 Prehabilitation

Prehabilitation is a proactive approach of involving patients actively in their care. There is ample evidence that prehabilitation improves outcomes early return of functional status [16–18]. The aim is to provide structured, individualised exercise regime to improve cardiorespiratory fitness and muscular conditioning. The exact mechanism is unclear, but it seems that a trained fit patient is better adept to deal with perioperative stress and sequelae. A multimodal strategy is superior to single modality in terms of functional recovery [17]. Taking into consideration of time sensitivity of an oncologic surgery, there a relative short window of opportunity to prehabilitation and optimisation of the patient. Prehabilitation has four components, such as medical optimisation, physical exercise and nutritional and psychological support. Medical intervention consists of optimisation of the co-morbidities such as hypertension, diabetes, asthma, management of anaemia etc.

8	
7	Extremely light
6	No exertion

Fig. 3 Borg scale of perceived exertion following exercise

Patients are encouraged to exercise. A baseline assessment of functional capacity is performed using CPET and the 6-min walk test. The exercise regime consists of 3–5 sessions per week of 30–60 min including a warm up and cool down time. Exercise typically prescribed is strength and aerobic training as cardiorespiratory fitness decrease in the postoperative period. The Borg scale of perceived exertion is a subjective tool often used during exercise testing and training to estimate effort based on how strenuous the exercise feels (Fig. 3). The target is typically in the range of 12–16.

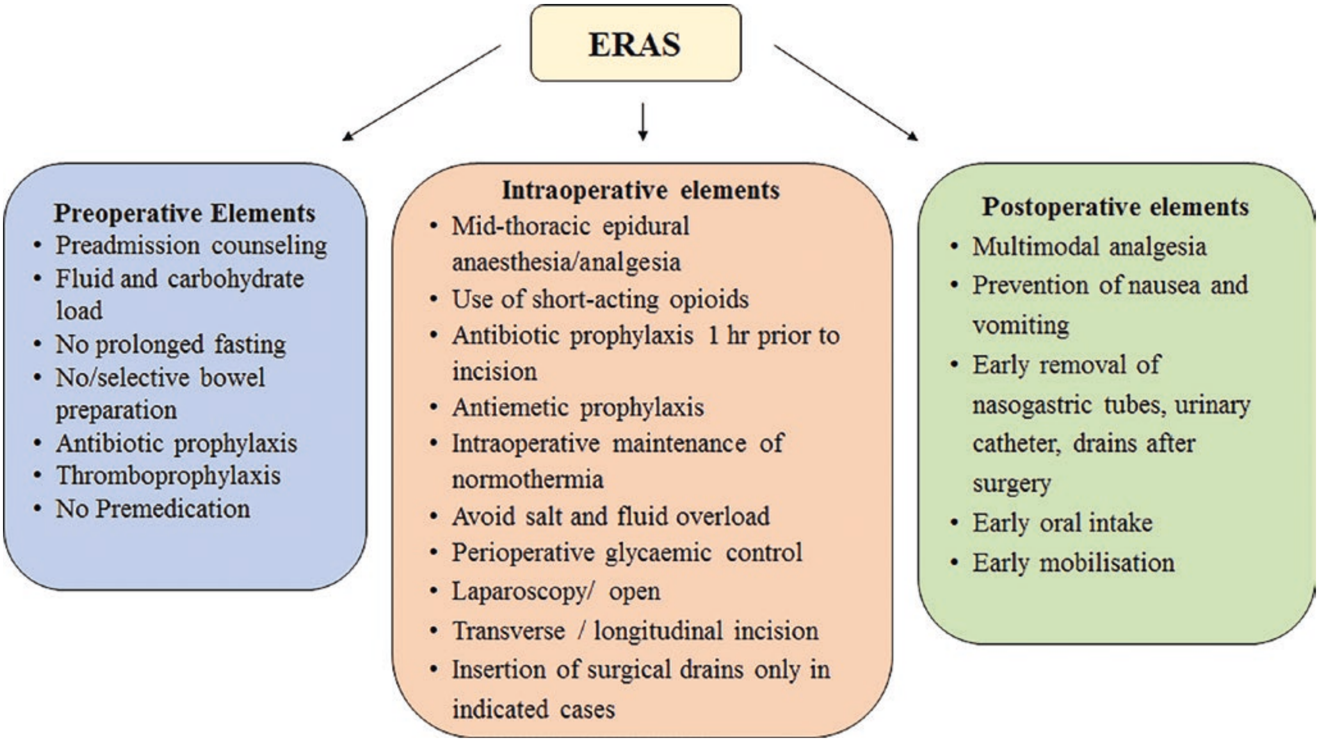
The goal of nutrition support is to optimise nutrient stores preoperatively and provide adequate nutrition to compensate for the catabolic response of surgery postoperatively. Preoperative nutritional support alone or in combination with preoperative exercise training has been associated with shorter postoperative stay in colorectal surgery. The European Society for Clinical Nutrition and Metabolism recommends 1.2–1.5 g protein/kg, for surgical patients. To be successful, preoperative nutrition support requires time and should be initiated early. A window of opportunity is the time period when decision for surgery is taken until the actual surgery and extends into the postoperative period [19].

Depression has been associated with infectious complications and poor wound healing [20]. Effective psychological and cognitive interventions provide information about what the patient's perioperative experience will feel like, development of positive attitude, behavioural instruction on what can be done to improve outcome, and relaxation techniques such as hypnosis and progressive muscle relaxation [21].

8 Anaesthesia and Enhanced Recovery After Surgery (ERAS)

Enhanced recovery (ER) conglomeration of different elements of care implemented perioperatively in patients undergoing elective surgery. The aim is to optimise patient's preoperative health to the best possible state before surgery, minimise perioperative stress response during surgery, early recovery and return to normal function and early recognition of abnormal recovery and intervention if necessary. Elements of an ERAS protocol are summarised in Fig. 4.

Compliance with ER elements has been associated with reduced morbidity and length of stay and cost with no impact on readmission across various surgical procedures such as colorectal, gynaecological, urological, pancreatic and liver surgery [22–29]. Quantitative impact of compliance to ER elements has demonstrated a favourable association with reduced morbidity, mortality and length of stay when the compliance was more than 80% with ER elements in patients undergoing pancreatic cancer resections [30].



ERAS
Preoperative Elements
• Preadmission counseling
• Fluid and carbohydrate load
• No prolonged fasting
• No/selective bowel preparation
• Antibiotic prophylaxis
• Thromboprophylaxis
• No Premedication
Intraoperative elements
• Mid-thoracic epidural anaesthesia/analgesia
• Use of short-acting opioids
• Antibiotic prophylaxis 1 hr prior to incision
• Antiemetic prophylaxis
• Intraoperative maintenance of normothermia
• Avoid salt and fluid overload
• Perioperative glycaemic control
• Laparoscopy/ open
• Transverse / longitudinal incision
• Insertion of surgical drains only in indicated cases
Postoperative elements
• Multimodal analgesia
• Prevention of nausea and vomiting
• Early removal of nasogastric tubes, urinary catheter, drains after surgery
• Early oral intake
• Early mobilisation

Fig. 4 Various components of ERAS in the perioperative period

9 Patient Blood Management

The European cancer anaemia survey found a prevalence of 25% in patients with head and neck cancer and 53% in those with a haematological cancer with a haemoglobin (Hb) cut-off 12 g/dL [31]. Patient blood management (PBM) is an evidence based multimodal, multidisciplinary clinical concept. It was developed in non-oncology patients with the aim to reduce perioperative blood transfusions and improve perioperative outcomes and patient safety. It consists of early diagnosis and treatment of anaemia before surgery, minimising intraoperative blood loss and harnessing physiological tolerance of anaemia in the postoperative period. The aim is to minimize use of allogenic blood transfusion and its associated immunomodulatory effects [32] (Table 4).

Table 4 Patient blood management in the perioperative period

	Preoperative	Intraoperative	Postoperative
Diagnosis and treatment of anaemia	Identify and treat anaemia at the earliest preferably 4–6 weeks before surgery. Consider oral or IV iron for absolute/functional iron deficiency. ESA can be used if after correction of iron deficiency if Hb below 10 g%; however, caution due to 1.5-fold increased risk of VTE in cancer patients [33]. Treat any vitamin B12/folate deficiency.	Identify and treat any pre-existing bleeding disorder. Review medications (antiplatelet, anticoagulation therapy). Minimise iatrogenic blood loss, i.e. repeated blood sampling.	Early nutrition and correct anaemia. Minimise iatrogenic blood loss, i.e. repeated blood sampling. IV iron can be administered to correct iron deficiency.
Minimisation of blood loss	If possible schedule surgery after optimisation of patient's Hb.	Central neuraxial blockade (has been shown to reduce blood loss during surgery). Proper patient positioning to improve venous drainage and reduce blood loss. Meticulous haemostasis in the surgical field. Maintain normothermia, ionic calcium >1 mmol/L, avoid acidosis pH <7.2. Use of antifibrinolytics such as tranexamic acid. Use goal-directed therapy for blood and blood products as per lab and visco-elastic testing.	Monitor and manage bleeding. Minimise iatrogenic blood sampling loss.
Management of anemia tolerance	Optimise cardiac and pulmonary function. Individualise patient-specific management for appropriate blood conservation modalities.	Use restrictive transfusion threshold if patients do not have major haemorrhage, ACS or need regular blood transfusions for chronic anaemia. Consider a threshold of 7 g% and a Hb concentration target of 7–9 g% after transfusion. Consider a threshold of 8 g% and a Hb target of 8–10 g% after transfusion for patients with ACS (NICE 2018, NG24).	Adhere to transfusion thresholds.

IV intravenous, *ESA* erythropoiesis-stimulating agents, *VTE* venous thromboembolism, *ACS* acute coronary syndrome, *NICE* National institute of Clinical Excellence guidelines

10 Intraoperative Techniques that Affect Postoperative Outcome

Fluid therapy and haemodynamic monitoring Patients undergoing major surgery are at high risk of tissue hypoperfusion and organ dysfunction due to the presence of inflammatory response, hypovolaemia and increased oxygen requirement. Fluid therapy is essential to restore tissue perfusion. However, excessive fluid intake has harmful effects by causing tissue oedema and reduced perfusion and has been associated with increased morbidity and mortality. On the other hand, excessive fluid restriction may lead to reduced tissue perfusion, delayed wound healing and renal dysfunction [34]. It has been suggested that haemodynamic monitoring should be used for goal-directed fluid therapy (GDFT). Invasive arterial pressure monitoring and use of haemodynamic strategies such as optimisation of fluid responsiveness parameters, stroke volume optimisation and optimisation of oxygen supply and demand parameters have been used for GDFT. A recent meta-analysis that included data from 95 trials and 11,659 patients found that GDFT was associated with significantly reduced odds of mortality (0.66, 95% confidence interval 0.50–0.87) and also reduced odds of pneumonia, acute kidney injury, wound infection and hospital length of stay [35].

Various other techniques with potential to affect postoperative outcome are as follows:

Protective lung ventilation strategy for mechanical ventilation during surgery [5]. It consists of ventilating with tidal volume 6–8 mL/kg of predicted body weight with positive end expiratory pressure (PEEP) 6–8 cm H_2O. Recruitment manoeuvre is done every 30 min after intubation. It is associated with 60% reduced risk of major pulmonary and extrapulmonary complications within 7 days compared to non-protective ventilation strategy, reduced need for non-invasive ventilation or tracheal intubation and shortened postoperative stay.

Individualised blood pressure management strategy [5]. Walsh et al. demonstrated that mean arterial pressure (MAP) < 55 mmHg predicted adverse cardiac- and renal-related outcomes [36]. Similarly, Salmasi et al. found that MAP <65 mmHg or relative thresholds of 20% from baseline were progressively related to both myocardial and kidney injury [37]. In view of adverse effects related to hypotension, maintaining systolic blood pressure (SBP) within 10% of patient's baseline SBP is associated with significantly lower rates of postoperative organ dysfunction. Vasopressors such as norepinephrine can be used to achieve blood pressure targets.

Maintaining normothermia (temperature 36–37 °C). Hypothermia has adverse effects on coagulation and the microcirculation and is associated with wound infections, myocardial ischaemia and blood transfusions. Therefore, patients should be kept warm in theatre, the recovery room and the ward for the first 24–48 h. This is best achieved by during surgery by using a warm air blanket and using warm fluids. Core temperature (nasopharyngeal or oesophageal) must be monitored during anaesthesia.

11 Anaesthesia for Head and Neck Surgery

Head and neck surgery for cancer includes a wide spectrum of surgical interventions, ranging from short day-case procedures like diagnostic endoscopies and laser excisions to very long and complex operations involving microvascular reconstructive surgery lasting over 12 h. Head and neck surgeries pose a special challenge to the anaesthetist due to risk of potential airway compromise, shared airway with surgeons, prolonged nature of surgery and associated blood loss. The greatest challenge is control of the airway throughout the perioperative period. Primary pathology and/or treatment can make the airway difficult. Therefore, inappropriate management can jeopardise ventilation and oxygenation resulting in morbidity or mortality. Clear communication within the team perioperatively is essential for a safe and satisfactory outcome.

Patients with perilaryneal tumours may present with stridor. Mild upper airway obstruction by a laryngeal tumour is often mistaken for "bronchospasm" in the initial stages and misdiagnosed as asthma. Stridor at rest is suggestive of a reduction in airway diameter by at least half, i.e. tracheal diameter less than 6 mm in adults. Stridor that worsens on extension of the neck or on gentle downward pressure on the larynx or inability to lie supine indicates severe obstruction. A flow-volume loop helps in identifying the location of obstruction (extrathoracic or intrathoracic) and the type of obstruction (fixed or variable). It is prudent to look at the findings of the most recent indirect laryngoscopy or endoscopic examination, and be familiar with the site, size and extent of the lesion. Large intraoral tumours, as well as those involving the right border of the tongue, base of the tongue and vallecula tend to bleed during laryngoscopy attempts and can make subsequent mask ventilation and intubation difficult. Presence of ankyloglossia signifies that the tongue is fixed and may not be easily displaced during direct laryngoscopy and likely difficult intubation. Trismus is a common in patients with oral cancers. Recent onset of painful trismus due to inflammation and infection associated with tumour may resolve after induction of anaesthesia. Long-standing trismus associated with submucous fibrosis, radiation-induced fibrosis of the temperomandibular joint, and tumour infiltration of the infratemporal fossa and pterygoid muscles is often painless and unlikely to improve after administration of a muscle relaxant making the airway difficult. Awake fibreoptic intubation is the safest airway management technique in such cases.

The anatomy of the patient's airway influences the choice of induction technique. Anaesthetic and surgical management of potential supra-glottic obstruction includes following options:

- Oral/nasal endotracheal intubation by videolaryngoscopy or direct laryngoscopy.
- Inhalation induction with endotracheal intubation.
- Intravenous induction with muscle relaxant with intubation.
- Tracheostomy under local anaesthesia.
- Recent techniques like the use of high flow oxygen by nasal cannula maintain oxygen for a longer duration (about 20 min) during apnoea, increasing the safety of the procedure and allowing surgical procedures of 20–30 min duration to be performed without intubation under apnoeic conditions [38].

Majority of these resections may require reconstructive surgery with either pedicle or free tissue transfer. The guiding principle of anaesthesia for reconstructive surgery is to maintain optimum blood flow. This can be achieved as follows:

- Traditionally, the use of hypervolaemic haemodilution was recommended during anaesthesia to maintain good flap blood flow by decreasing viscosity, increasing cardiac output and avoiding vasoconstriction. However, free flaps have no lymphatic drainage thus are prone to interstitial oedema and excessive fluid administration may in fact be detrimental. Haemodilution enhances microcirculatory flow. Haematocrit below 30% does not provide any further benefit as the curve of viscosity versus haematocrit flattens off markedly. If the haematocrit falls below 24%, the marginally improved flow characteristics from a lower viscosity may then be offset by a reduction in oxygen delivery. Therefore, normovolaemia should be maintained.
- Avoiding hypothermia and hypocapnia prevents vasoconstriction. Hypocapnia increases peripheral vascular resistance and reduces cardiac output. The aim is to maintain normothermia and normocapnia.
- Isoflurane has the advantage over other volatile anaesthetics as it causes vasodilatation with minimal myocardial depression. Propofol inhibits platelet aggregation and reduces the risk of thrombosis. In experimental studies, sevoflurane has been shown to have beneficial effects on the microcirculation by decreasing extravasation of plasma into the interstitial space, and thus limiting flap oedema.

Common postoperative problems are airway compromise, airway injury, haemorrhage, pulmonary aspiration and negative pressure pulmonary oedema after relief of airway obstruction. The airway must be secured until complete recovery of reflexes and higher functions to protect the airway against obstruction and aspiration. Patients are transferred to the post anaesthesia care unit with the tracheal tube in situ and extubated when the patient is wide-awake with intact reflexes. Elective ventilation may be required in case of massive blood loss or hypothermia, till the temperature normalises, effects of all anaesthetic drugs have worn off and patients are haemodynamically stable. Tracheostomy is preferred in cases of resection of floor mouth, resection > two-thirds of tongue, when mandibular resection has crossed the midline, in presence of bulky flaps that occupy a large part of the oral cavity or if there are limited postoperative resources to manage airway problems.

12 Laser Resections for Airway Tumours

Laser resection may be used in patients with pharyngeal, tracheal or bronchial strictures or for palliation of airway tumours. Carbon dioxide (CO_2) and NdYAG (neodymium-doped yttrium aluminum garnet) lasers are commonly used. The CO_2 laser is characterised by limited tissue penetration, which restricts its use to localised lesions of the upper airway. In contrast, the NdYAG laser exhibits enhanced tissue penetration and can be transmitted through fibreoptic bronchoscope; therefore, it is much more effective for the ablation of large masses in the trachea and bronchi. The requirements during anaesthesia for laser surgery are complete patient immobility, shared airway with surgeon, un unrestricted surgical access, protection of distal airway against blood and products of vaporisation, protection of patient and staff from stray laser radiation/reflection, removal of smoke and debris and prevention of airway fires. Maintenance of airway and mode of ventilation depend upon the site of the target lesion. For laryngeal lesions, the procedure is often performed using the operating microscope. Ventilation is often possible via an endotracheal tube as in micro-laryngoscopy. When the tracheal tube interferes with the surgical resection, as with lesions of the posterior commissure, bulky lesions and in children, apnoeic oxygenation with intermittent ventilation with venturi or breathing circuit can be done.

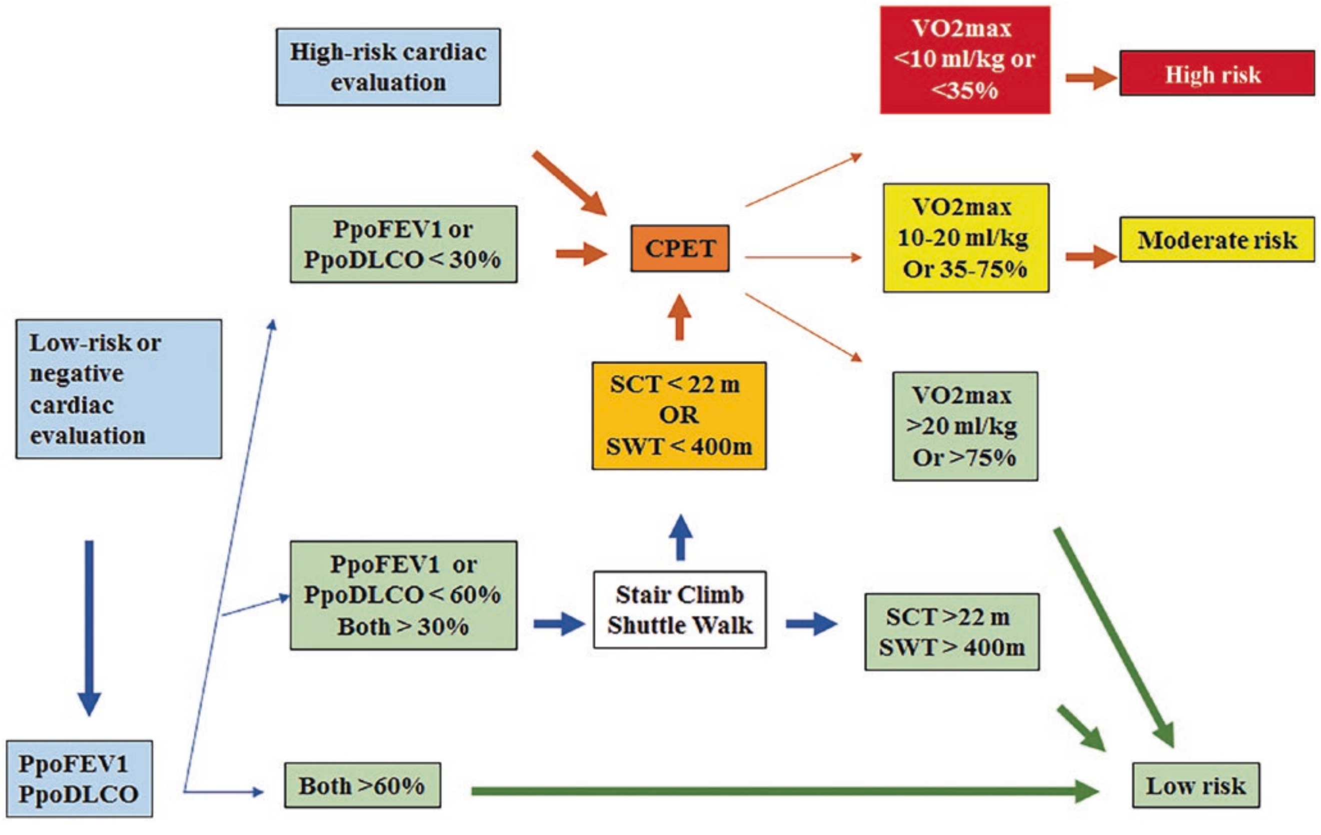
Small-diameter, laser-resistant cuffed tubes can be used. Polyvinyl chloride tubes are readily flammable and combustion products are tissue toxic and hence should not be used in these types of surgeries. Red rubber tubes are more fire resistant and burn slowly. Wrapping these tubes with aluminium foil makes them fire resistant; however, if the laser beam gets accidentally directed onto the foil, it gets scattered and can cause damage to the surrounding normal mucosa. Endotracheal tube cuff is filled with saline/water to decrease chances of fire should the laser beam strike the cuff. Also, wet cotton pledgets are placed on the cuff by the surgeons to prevent the laser beam inadvertently striking the cuff.

It is prudent to use a gas mixture of air and oxygen instead of nitrous oxide as it supports combustion. Also inspired oxygen concentration of less than 30% should be used. In case of airway fire, the anaesthesia circuit should be immediately disconnected and the surgical site flooded with sterile normal saline. After through suctioning, the damaged tube is removed and replaced with a fresh tube. The patient is ventilated with 100% oxygen, and the damage in lower airway is assessed by fibreoptic bronchoscopy. The patient should be given steroids, humidified oxygen and supportive care.

13 Anaesthesia and Thoracic Surgery

Anaesthesia for major thoracic surgeries is highly specialised and covers a spectrum of procedures such as lung resection, oesophagectomy, chest wall tumour excision and resection of mediastinal mass. A majority of patients presenting for lung resections for malignancy are smokers and may have end-organ damage related to the effects of smoking such as chronic obstructive pulmonary disease or ischaemic heart disease. Careful risk stratification and optimisation are needed in these patients. A scheme for preoperative evaluation for lung resection surgery is depicted in Fig. 5.

In patients with mediastinal mass, careful review of the scans and discussion with the surgeons to look for involvement of major airways and vascular structures is important. Induction of general anaesthesia can precipitate airway obstruction, which is worsened by positive pressure ventilation. Airway obstruction may occur at the level of the distal trachea or main bronchus and can result in complete failure to ventilate the patient. Supraglottic devices or tracheostomy cannot salvage this situation, and rigid bronchoscopy may be the best rescue option to restore ventilation. Flow-volume loops do not help in risk stratification for severe airway obstruction, which is best done by evaluation of symptoms and the CT scan. Low-risk patients are asymptomatic and have no tracheal compression on the CT scan. High-risk patients, such as



High-risk cardiac evaluation
VO2max <10 ml/kg or <35%
High risk
PpoFEV1 or PpoDLCO < 30%
CPET
VO2max 10-20 ml/kg Or 35-75%
Moderate risk
Low-risk or negative cardiac evaluation
SCT < 22 m OR SWT < 400m
VO2max >20 ml/kg Or >75%
PpoFEV1 or PpoDLCO < 60% Both > 30%
Stair Climb Shuttle Walk
SCT >22 m SWT > 400m
PpoFEV1 PpoDLCO
Both >60%
Low risk

Fig. 5 Preoperative evaluation for lung resection surgery [39]. *Ppo* predicted postoperative, *FEV1* forced expiratory volume in 1 s, *DLCO* diffusing capacity for carbon monoxide, *SCT* stair climbing test, *SWT* shuttle walk test, *VO2max* maximum oxygen consumption, *CPET* cardiopulmonary exercise test

children with >50% tracheal compression, are severely symptomatic, may present with stridor or cyanosis, severe postural symptoms, pericardial effusion or the superior vena cava syndrome. General anaesthesia should be avoided if possible, especially in high-risk cases. Spontaneous ventilation should be maintained as far as possible. If the airway obstruction is extremely severe, cannulation and preparation for cardiopulmonary bypass should be considered before induction of anaesthesia and not after total airway obstruction and severe hypoxemia have set in [40].

Certain thoracic procedures need separation of the lungs for better surgical access and for control of ventilation. The most common techniques used for lung isolation are double lumen tubes (DLT), endobronchial blockers (EBB) and endobronchial single-lumen tubes. DLTs have traditionally been considered the gold standard for lung isolation; the advantages are faster lung collapse, better quality of suctioning, lesser malposition and ability to ventilate either lung. A variety of EBBs are currently available and their advantages include less trauma, ability to offer selective lobar blockade and useful in a patient with difficult airway. Endobronchial intubation with a single lumen tube is inferior to either of the above techniques since it does not allow ventilation or suctioning of the isolated lung and should be considered only as the last option.

Collapse of the isolated lung during one-lung ventilation creates an obligatory shunt with resultant hypoxemia. Physiological techniques to overcome this hypoxemia include patient positioning (with the collapsed lung non-dependent to allow gravitational decrease in perfusion) and hypoxic pulmonary vasoconstriction. If these measures fail, introduction of ventilatory strategies like recruitment manoeuvres, application of PEEP to the ventilated lung and CPAP to the non-dependent lung should be considered. With increasing understanding of lung injury during one-lung ventilation, the emphasis is on lung protective ventilation using low tidal volumes (4–6 mL/kg predicted body weight), PEEP, recruitment manoeuvres, use of inhaled anaesthetics (sevoflurane) and lowest tolerated FiO_2. Intra-operative complications can be mainly due to hypoxemia during one-lung ventilation, bleeding from vascular injury and haemodynamic instability compounded by direct mechanical retraction of the heart or arrhythmias.

Both thoracotomy and thoracoscopy are associated with significant acute and chronic pain, which is multifactorial in aetiology and arises from rib retraction, pressure on intercostal nerves and positioning. Thoracic epidural analgesia has been considered the gold standard for thoracotomy. Paravertebral blocks have been described as an effective alternative. There is growing interest in the role of fascial plane blocks such as the erector spinae block and the serratus plane block [41].

14 Unique Onco-Surgical Procedures

Certain procedures are unique to cancer patients such as cytoreductive surgery with or without hyperthermic intraperitoneal chemotherapy (HIPEC), proton therapy, robotic surgery for various malignancies. These will be discussed briefly below covering main aspects of anaesthetic implications [42].

14.1 Cytoreductive Surgery with Intraoperative Chemotherapy (Hyperthermic Intraperitoneal Chemotherapy [HIPEC] and Hyperthermic Intra-thoracic Chemotherapy [HITHOC])

It involves extensive resection of visible tumour followed by direct exposure of microvascular residual disease to hyperthermic (42–45 °C) chemotherapy. Heated chemotherapy causes direct thermal injury to cancer cells in addition to immune-mediated cytotoxicity. Chemotherapeutic agents such as mitomycin C, cisplatin, oxaliplatin and doxorubicin are used. Hyperthermic phase can vary from 60 to 90 min. Currently, HIPEC is being considered for peritoneal carcinomatosis, mesothelioma, desmoplastic small round-cell tumours, ovarian, colorectal and gastric malignancies. This procedure involves extensive abdominal/thoracic resection, which causes massive fluid shift, bleeding, coagulation abnormalities, electrolyte and metabolic derangements. Pre-anaesthetic assessment and workup should focus on the patient's ability to withstand these disturbances in physiology. Pulmonary function tests should be done for these patients to evaluate the pulmonary reserve.

Before initiation of HIPEC, the patient is made hypothermic up to 35 °C by using cold packs around the head, neck and axilla and by turning forced air warmers to ambient temperature. During the HIPEC phase, because of hyperthermic chemotherapy, the temperature increases and causes a hypermetabolic state, which is associated with hyperdynamic cardiovascular state with increased oxygen demand. As a consequence, metabolic acidosis is often seen which gradually clears in the postoperative phase. Patients should not be hypovolaemic before initiation and during the HIPEC phase to avoid nephrotoxicity due to platins. Cold intravenous fluids may be infused to prevent the core body temperature from rising above 39°C. Dextrose is used as a carrier solution for oxaliplatin, which is hypotonic and causes hyperglycaemia and hyponatraemia. Therefore, blood glucose and electrolytes need to be monitored frequently and corrected. The patient is often electively ventilated due to prolonged surgery.

14.2 Robotic Surgery

The role of robotic surgery is increasing due to improved surgical precision and the growing need for minimally invasive surgery. Robotic surgery is mainly used for pelvic malignancies and head and neck procedures. However, its scope is increasing and is currently being used for abdominal and thoracic surgery as well.

Important considerations for robotic surgery are mainly patient access and extreme positioning and its consequences. It is imperative to plan ahead for vascular access and extensions, and airway access and circuit extensions, as once the robot is docked there is not much scope to do any procedures. These are often prolonged surgical procedures and extreme positioning such as steep Trendelenburg or reverse Trendelenburg with a left or right tilt, is used for improved access for pelvic and abdominal procedures. Careful planning and attention should be given to padding of pressure points and haemodynamic disturbances due to position. This is compounded by the effect of pneumoperitoneum. Carbon dioxide insufflation can result in basal atelectasis and respiratory compromise, hypercapnia, reduced venous return, cardiac output and hypotension, and sympathetic stimulation. In Trendelenburg position, after prolonged surgery there is an increase in cerebral blood flow, intracranial pressure and venous congestion, resulting in swelling of the eyes and face and airway oedema; therefore, extubation strategy should be planned.

14.3 Proton Radiation Therapy

High-energy protons allow more accurate targeted delivery of energy to disease tissues thus sparing healthy tissues. These protons unlike conventional radiation deposit energy at the end of their path thus proton therapy has application in deep seated tumours such as those of the central nervous system. It is also used for treatment of paediatric retinoblastoma, prostate and bladder cancers and hepatocellular carcinoma. It consists of multiple treatment sessions (10–30), and the duration of each session may last up to 90 min. Due to longer treatment sessions, recovery of these patients may be delayed and therefore an adequately staffed recovery is essential. It also requires immobilisation devices like cradles and thermoplastic facemasks. Therefore, children and claustrophobic adults may require deep sedation for treatment sessions. Careful attention should be given to patient positioning during treatment as posterior fossa tumours may require prone positioning. Tight-fitting immobilisation facemasks may lead to airway compromise.

15 Acute Pain Management After Cancer Surgery

Poorly managed postoperative pain delays mobilisation, increases postoperative respiratory and thromboembolic complications and delays rehabilitation [43]. Effective pain relief helps with early mobilisation of patient, shortened hospital stay, reduced cost and improved patient satisfaction [44, 45].

An 11-point numerical pain assessment scale, where 0 is no pain and 10 is the worst possible pain imaginable, is used to quantify pain. The “Faces pain scale” is effective in those with language barrier and children above 4 years of age. The goal is to relieve pain with minimal side effects. The key to adequate pain control is to reassess the patient and determine if they are satisfied with the outcome.

Current evidence supports a multimodal approach to reduce opioid side effects (such as nausea and ileus) and improve pain scores. Multimodal analgesia uses a combination of analgesics or techniques each with a different mode of action; thereby lowering side effects by a reduction in analgesic doses, particularly of opioids. It usually consists of a combination of opioid and non-opioid analgesics with or without a regional block. Regional anaesthesia including wound infiltration, perineural injections, truncal/fascial plane blocks (e.g. transversus abdominis plane block, rectus sheath block), spinal and epidural analgesia are valuable components of multimodal approach [46, 47].

Epidural analgesia using local anaesthetics with or without an opioid provide superior analgesia than most other techniques and is used extensively in thoracic, abdominal and pelvic surgery. Epidurals are often used in high-risk surgeries with recent evidence showing improved pain control in the first 72 h compared to systemic opioids and positive effects on cardiac and pulmonary outcomes [48]. Of concern with epidural analgesia/anaesthesia is the insertion and removal of catheters in patients on oral or parental anticoagulants and antiplatelet agents because of an associated risk of neuraxial haematomas. The risk can be minimised by timing the same to the dose of the anticoagulant as briefly mentioned in Table 5.

Opioids such as morphine or fentanyl can be administered through the patient-controlled analgesia (PCA) device, special equipment that gives patient better control and autonomy over the amount of analgesic used. PCA is essentially a maintenance therapy; therefore, before initiating the PCA individually titrated doses should be administered, for optimum pain relief.

NSAID’s and paracetamol are useful in reducing opioid requirement and their side effects. Systematic reviews of randomised controlled trials (RCTs) have confirmed efficacy

Table 5 Guidance on timing of insertion and removal of epidural in patients on anticoagulant and antiplatelet medications[a]

	Minimum delay between last dose and placement or removal of epidural catheter	Minimum delay after placement or removal of epidural catheter and subsequent dosing
Heparin		
• No contraindication. • The risk of neuraxial bleeding may be increased in debilitated patients after prolonged therapy. • Patients receiving heparin for >4 days should have a platelet count assessed prior to neuraxial block and catheter removal (to rule out heparin-induced thrombocytopenia—HIT).		
IV Unfractionated heparin (UFH)	4–6 h	2 h
SC unfractionated heparin BD/TID dosage		
• Low dose (5000 U twice/thrice daily)	4–6 h	2 h
• High dose (<20,000 U/day)	12 h	Assess risk/benefit ratio
• Therapeutic dose (>20,000 U/day)	24 h	Assess risk/benefit ratio
Full anticoagulation of cardiac surgery	Currently, insufficient data and experience. Postoperative monitoring of neurologic function and selection of neuraxial solutions that minimise sensory and motor block is recommended to facilitate detection of new/progressive neurodeficit.	
Low-molecular-weight heparin (LMWH) **Dalteparin, enoxaparin, tinzaparin, etc.**		
Twice-daily dosing	24 h	4 h Avoid indwelling catheters during initiation of prophylactic or therapeutic BD dosing
Single-daily dosing	12 h	4 h Post op dose 12 h after epidural placement with catheter in situ
Traumatic needle or catheter placement may signify an increased risk of spinal haematoma, and it is recommended that this consideration be discussed with the surgeon. It does not necessitate postponement of surgery. However, initiation of LMWH therapy in this setting should be delayed for 24 h postoperatively.		
• Routine use of monitoring of the anti-factor Xa level is not recommended. • Antiplatelet or oral anticoagulant medications administered in combination with LMWH increase the risk of spinal haematoma. • Patients receiving LMWH for greater than 4 days should have a platelet count assessed prior to neuraxial block or catheter removal to rule out HIT.		
Warfarin		
• Stop warfarin at least 5 days prior to procedure. • Bridge with heparin infusion if continued anticoagulation is required. • Check INR on day of procedure and ensure <1.5 INR. • If INR >1.5. (a) Delay surgery (b) If surgery is urgent—consider alternative anesthetic/analgesic technique or reversal with 2.5–5 mg PO/IV vitamin K. (c) For emergency procedure consider reversal with fresh-frozen plasma/prothrombin complex concentrates. • Consider removal of neuraxial catheter prior to starting oral warfarin.		
Fibrinolytics/thrombolytics **(Alteplase, reteplase, tenecteplase, urokinase and streptokinase)**		
Absolute contraindication for neuraxial blockade • Thrombolytics drugs are contraindicated for 10 days following puncture of non-compressible vessels. • In patients who have received fibrinolytic and thrombolytic drugs, we recommend against performance of spinal or epidural anaesthetics. • Patients with epidural catheter who **unexpectedly receive fibrinolytic and thrombolytic therapy, fibrinogen level should be monitored to evaluate the presence of residual thrombolytic effect for appropriate timing of catheter removal.**		
Antiplatelet drugs		
Aspirin, –anti-inflammatory drug (NSAID's), cyclo-oxygenase inhibitors (COX2)	0 day in absence of other anticoagulant co-administration. Caution with performance of neuraxial techniques with concurrent use of other medications affecting clotting mechanisms, such as other (non-NSAID) antiplatelet agents, oral anticoagulants, UFH and LMWH.	
Antiplatelet drugs (P2Y12 receptor inhibitors)		
Clopidogrel	7 days	Daily maintenance dose take 6 h later Loading dose 24 h later
Ticlopidine (rarely used now)	10 days (10–14 days)	6 h
Prasugrel	7–10 days	6 h

(continued)

Table 5 (continued)

	Minimum delay between last dose and placement or removal of epidural catheter	Minimum delay after placement or removal of epidural catheter and subsequent dosing
Ticagrelor	5–7 days	6 h
Cangrelor	3 h	8 h
Antiplatelet drugs (GP IIb/IIIa antagonists) **AVOID due to platelet dysfunction**		
Abciximab	24–48 h	AVOID (if necessary, monitor neurological function)
Tirofiban	4–8 h	
Eptifibatide	4–8 h	
Other antiplatelet agents		
Dipyridamole	24 h	6 h
Cilostazol	2 days	6 h
Anti-Factor Xa—Fondaparinux		
Fondaparinux	36 h	12 h
Fondaparinux is recommended for thromboprophylaxis only with single needle pass, atraumatic needle placement and avoidance of indwelling neuraxial catheters. If this is not feasible, an alternate method of prophylaxis should be considered.		
Newer oral anticoagulants (factor Xa inhibitors)		
Rivaroxaban	Catheter placement after 72 h and removal after 22–26 h	6 h
Apixaban	Catheter placement after 72 h and removal after 26–30 h	6 h
Edoxaban	Catheter placement after 72 h and removal after 20–28 h	6 h
Betrixaban	Catheter placement and removal after 72 h Avoid neuraxial block if creatinine clearance (CrCl)l < 30 mL/min	5 h
Direct thrombin inhibitors		
Parenteral, e.g., desirudin, bivaluridin, argatroban	AVOID	–
Oral dabigatran	Catheter placement after 120 h CrCl > 80 mL/min–72 h CrCl—50–79 mL/min–96 h CrCl—30–50 mL/min—120 h CrCl < 30 mL/min—AVOID **Consider checking dilute thrombin time (dTT) or ecarin clotting time (ECT) if less than recommended duration**	6 h For patient with unanticipated administration with indwelling catheter **dabigatran dosing should be held for 34–36 h or the dTT or ECT should be assessed before removal.**
Herbal remedies (check for concomitant other blood thinners)		
Garlic	Stop 1 week prior, also stop other antiplatelet agents	
Dong quai/Danshen	Check INR with warfarin	
Ginkgo biloba	Check platelet function, discontinue 36 h before surgery	
Ginseng	Check coagulation profile, discontinue 24 h before surgery	

[a] Adapted from American Society Regional Anaesthesia guidelines [49]

of oral paracetamol for acute pain. Care should be taken not to exceed the 4000 mg per day limit due to risk of hepatotoxicity.

16 Adjuvants

“Adjuvant analgesics” are drugs with a primary indication other than pain, but are analgesic in some conditions. Central sensitisation through the descending pathway causes hyperexcitability in the spinal cord, which is thought to be responsible for chronic and neuropathic pain. Dampening of central sensitisation is important for prevention and treatment of both acute postoperative and chronic pain. These drugs are often used as part of multimodal analgesia, to achieve superior analgesia with lesser side effects. Various drugs used as adjuvants are listed below in Table 6.

Table 6 Adjuvant drugs for management of postoperative pain

Drug	Mechanism of action	Dose	Benefits	Concerns/cautions
Ketamine	Non-competitive NMDA receptor antagonist blunts central pain sensitisation at sub-anaesthetic doses.	Intraoperative IV bolus of 0.1–0.3 mg/kg alone or followed by postoperative infusion of 0.1–0.3 mg/kg/h for 24–72 h.	Its use is associated with reduction in the need/dose of other postoperative pain medications and pain scores [50]. May prevent development of persistent post-surgical pain however effective doses are yet to be established [51, 52].	May cause hallucinations and postoperative dissociative mental state. Contraindicated in patients with high-risk coronary or vascular disease, uncontrolled hypertension, intracranial or intraocular pressure, globe injuries, history of psychosis, sympatho-mimetic syndrome, hepatic dysfunction, recent liver transplantation and porphyria.
Lignocaine	It has analgesic, anti-inflammatory, and anti-hyperalgesic properties possibly mediated by inhibition of Na channels, NMDA and G-protein-coupled receptors.	IV Lignocaine, bolus of 1.5–2 mg/kg followed by an infusion of 2–3 mg/kg/h in the perioperative period and at a lower dose postoperatively.	Reduced opioid requirements and improved recovery of bowel function [50].	Lignocaine toxicity. Quality of evidence is limited due to inconsistency and quality of study [53].
Gabapentinoids Gabapentin	Decrease the dorsal horn sensitivity by inhibiting calcium-mediated neurotransmitter release through effects on α2δ-1 subunits. They also • Inhibit descending serotonergic facilitation • Stimulate descending inhibition • Have anti-inflammatory actions • Influence affective component of pain [54].	PO 600–1200 mg/day Max 1500 mg/day Administered 1–2 h prior to the surgery [50].	Associated with reduced opioid requirements and lower pain scores [50, 55].	Side effects such as dizziness, sedation, somnolence, with the higher doses. Dose should be adjusted in elderly and impaired renal function.
Pregabalin		150–300 mg/day administered 1–2 h prior to the surgery [50].		
Magnesium	Blockade of NMDA receptor and calcium channel.	IV bolus 50 mg/kg in 100 mL of normal saline given over 15 min during induction of anaesthesia followed by a continuous infusion at 15 mg/kg/h during surgery was found to significantly reduce postoperative pain.	Perioperative infusion has shown to reduce opioid consumption and pain scores in the first 24 h with no serious side effects [56].	Bradycardia, hypotension,muscle weakness and potentiation of non depolarising muscle relaxants, ECG changes such as prolongation of PR & QT intervals. Should be used with caution and avoided in those with pre existing AV blocks and chronic neuromuscular diseases such as myasthenia graves.

NMDA N-methyl-D-aspartate, *PO* per-oral, *IV* intravenous

17 Anaesthesia and Cancer Recurrence

Advances in surgery, chemotherapy, and radiotherapy have improved outcomes after surgery for cancer. However, cancer cells that may be released into the circulation during surgery may lead to cancer recurrence and metastases. Anaesthetic drugs and techniques may significantly contribute to this process and thereby present an opportunity for intervention.

Surgery, perioperative stress, anaesthetics and analgesics may modulate the immune-surveillance mechanisms and overwhelm host defences that normally maintain a balance between immunity and carcinogenesis. This may lead to escape of cancer cells and tilt the scales towards a more pro-tumorigenic micro-environment. Choice of anaesthetic technique and drugs used in the perioperative period has been an area of interest in the last few years, as they may affect postoperative immune function and inflammation which may have a role in cancer progression and metastasis. Volatile anaesthetic agents, in particular, have been shown to exhibit profound immunosuppressive effects and may be associated with adverse long-term outcomes compared to total intravenous anaesthesia (TIVA). In comparison, propofol has a favorable profile and inhibits cancer cell activity. Opioids suppress natural killer (NK) cell function as well as have inhibitory effect on T and B lymphocyte functions by direct and indirect mechanisms [57], thus promoting tumour recurrence and metastases.

Ketamine in low dose suppresses NK-cell cytotoxicity and inhibits the production of pro-inflammatory cytokines [3, 58, 59]. Endogenous and exogenous opiods have differing effects on the immune balance. Endorphin increases NK-cells cytotoxicity and favours anti-inflammatory cytokines and has anti-cancer effects. Exogenous opioids on the other hand suppress the immune function by inhibiting humoral and cell-mediated immunity (CMI) and promote cancer cell proliferation and angiogenesis [58]. Propofol inhibits tumour size, angiogenesis of cancer and does not suppress CMI thus has an anti-cancer effect [58, 59]. Local anaesthetics attenuate afferent neural transmission by sympathetic blockade and thus prevent pain and reduce neuroendocrine stress response and thus preserving CMI. They may directly stimulate natural NK-cell activity. Local anaesthetics block voltage-gated sodium channels and thereby prevent activation of prometastatic pathways. In addition, use of regional anaesthesia reduces the dose of exogenous opioids and volatile anaesthetics suggesting a favourable effect on the perioperative immune balance [58, 60].

Despite animal studies, there is very little human data to conclude that a particular anaesthetic is associated with worse clinical outcomes [61, 62]. A randomised trial found that regional anaesthesia-analgesia with paravertebral block and propofol sedation for surgery did not reduce breast cancer recurrence compared to general anaesthesia with volatile anaesthesia (sevoflurane) and opioids [63]. These data suggest that genral anaesthesia with opioids and volatile agents can safely be used for cancer surgery. However, regional anaesthesia and intravenous anaesthesia with propofol should be used where appropriate for clinical indications.

18 Conclusion

Elderly patients with sedentary lifestyle and multiple comorbidities along with cancer therapy adversely affect overall physical fitness and nutrition which in turn are associated with poor postoperative outcomes. Perioperative care plans should take this into consideration and should be individualised to improve physical fitness, optimise medical conditions and anaemia, implementation of evidence-based and outcome driven perioperative care pathways to promote early recovery and reduced morbidity. Preclinical studies suggest that anaesthetic-induced immunosuppression may affect tumour biology and promote cancer recurrence in patients with certain types of cancer. Causal link between anaesthetic techniques on residual disease, immune function, survival is yet to be elucidated. Future research in this area will provide more definitive answers.

Transfusion Medicine in Oncology

Priti Desai, Anisha Navkudkar, and Sunil Rajadhyaksha

1 Introduction

Blood transfusion therapy is complex and multifaceted. Though the general principle of transfusion therapy is same to all patients, special considerations are required for oncology patients. Transfusion support is required for oncology patients during their course of treatment as they undergo chemotherapy, radiotherapy, and surgical intervention [1]. Oncologic conditions may induce myelosuppression resulting in anemia, thrombocytopenia, and granulocytopenia during the treatment course. Hence, these patients require all kinds of blood transfusion support. It is therefore critical that blood transfusion services should be able to provide the necessary hemotherapy support in consultation with the oncologists. Although the introduction of recombinant hematopoietic growth factors and peripheral stem cell transplant has decreased the need of blood products, it has not eliminated the need of blood component therapy. Transfusion of blood components is associated with adverse events hence probable benefits of transfusion must be assessed against risks associated. Evidence-based medicine (EBM) enhances clinical decision making by incorporating best research evidence with clinical proficiency and patient parameters [2].

2 History of Transfusion Medicine in India

The first blood bank in India was established in Kolkata at the All-India Institute of Hygiene and Public Health in 1942 and was shifted to Kolkata Medical College, as the first civilian blood bank in the country in 1945 [3]. In earlier times, till 1970 collected blood was stored in bulky and fragile glass bottles which had to be washed and sterilized for reuse. With the glass bottles, separation into different blood components was complicated, lacked consistency, and prone to bacterial contamination. Subsequently, plastic bags made separation of blood much easier, allowing focussed management of conditions such as anemia and bleeding especially in treatment of patients with leukemia and lymphoma who underwent aggressive chemotherapy and bone marrow transplantation. With the establishment of disposable plastic blood bags, blood components could be stored and transported more easily. Blood transfusion services have transcended from initial process of withdrawal of blood, storage, and transfusion to complex laboratory technologies, patient care and evidence-based management. The blood center-based services include serological aspects of blood, advanced immunohematology techniques, preparation of blood components, modification of blood components, multicomponent therapy, testing for transfusion transmissible infections (TTIs), nucleic acid amplification testing (NAT), and research of several aspects of blood safety. Apheresis technology, cellular therapies, and novel immunotherapies are included in patient care services. Blood donor motivation, recruitment, retention, rare donor registries, and apheresis donors are crucial challenging tasks in blood transfusion services. Evidence-based medicine is forming the basis of clinical transfusion practices these days. Also, hemovigilance and transfusion audits are important for optimum patient services. The comprehensive, centralized, and a well-organized Hemovigilance program of India generates evidence-based suggestions for transfusion safety and precautionary measures [4, 5].

3 History of Transfusion Medicine in Oncology

Transfusion support is an important supportive therapy for patients with hemato-oncologic disorders. Due to the myelosuppression and immunosuppression, they require multiple blood transfusions and at risk for transfusion related adverse events. Hemato-oncologic patients are at increased risk for

alloimmunization, certain transfusion transmitted infections (TTIs), transfusion-associated graft vs. host disease (TAGVHD), and transfusion-related immunomodulation (TRIM) as compared to the general patient population. Also, transplant patients might pose unique challenges to blood transfusion services due to potential ABO incompatibility in some cases. Therefore, appropriate therapy to these patients is provided by careful selection and modification of blood components as per the requirements. The transfusion safety in oncology patients is improved by significant advances in transfusion therapy including advanced immunohematology techniques for antibody identification and providing appropriate blood components.

4 Physiological Aspects of Blood

4.1 Red Cell Kinetics

The primary function of red blood cell is to transport oxygen from lungs to other tissues of the body. Oxygen delivery is regulated by number of circulating erythrocytes in the blood, which depends on rate of aging erythrocyte removal and rate of reticulocyte entry. Normal bone marrow produces almost precisely the same quantity of erythrocytes daily as lost through senescence. When increased amount of erythrocytes are lost in bleeding or hemolysis, new erythrocyte production rapidly increases to maintain constant erythrocyte number. The regulated production of erythrocyte is controlled by negative feedback mechanism, which involves oxygen supply and consumption, the hormone erythropoietin (EPO) produced in the kidneys, and the erythroid progenitor cells in the bone marrow dependant on EPO. It also depends on sufficient supplies of specific nutrients like iron, folate, and vitamin B_{12}. Disorders of hematopoietic system like malignancy inhibit the erythropoietic process.

4.2 WBC Kinetics

WBCs especially neutrophils are the body's main defence cells against bacterial organisms. Increased neutrophil counts are typical of infections, chronic myeloid leukemia and other myeloproliferative disorders (MPD) and reduced neutrophils can indicate aplastic anemia, myelodysplastic syndrome (MDS), acute leukemia, and other disorders affecting bone marrow function. Production and differentiation of neutrophils and other granulocytes are labeled as myelopoiesis or granulopoiesis. It is controlled by hematopoietins and cytokines which stimulate colony formation from progenitor cells in the bone marrow. Granulocyte colony-stimulating factor (G-CSF) is the primary cytokine-regulating granulopoiesis, as it stimulates granulopoiesis at various stages of granulocytic differentiation. GCSF significantly expands the marrow neutrophil mitotic pool and reduces the transit time of the post mitotic pool. Mean marrow neutrophil transit time of a postmitotic pool in healthy person is 6.4 days, whereas with G-CSF it is 2.9 days [6].

4.3 Platelet Kinetics

Platelet production or megakaryocytopoiesis starts with hematopoietic stem cells (HSCs) commitment toward megakaryocyte lineage and involves proliferation, maturation, and differentiation of megakaryocytic progenitors. The primary growth factor for the expansion of megakaryocyte (MK) lineage is thrombopoietin (TPO), which induces concentration determined proliferation and maturation of megakaryocyte. The key transcription factors involved in common myeloid precursor (CMP) are PU.1, which regulates granulocyte-monocyte progenitors, and GATA-1, which leads to differentiation of megakaryotic-erythroid precursors (MEPs) [7]. The normal platelet production kinetics is indirectly measured by establishing the turnover rate of circulating platelets. The lifespan of platelets is 9.5 ± 0.6 days and platelet loss is usually linear. Reticulated platelets are the platelets, which are newly released from megakaryocyte into circulation. They are characterized by increased RNA content and reflects on thrombopoietic activity of bone marrow [8]. An increase in reticulated platelets is observed whenever there is peripheral destruction of platelets and decrease in number is seen in case of hypoproliferative disease of marrow such as marrow aplasia due to chemotherapy, radiation, or aplastic anemia.

4.4 Normal Hemostasis

Hemostasis is the physiologic process that halts bleeding after injury to the vessel and depends on cellular components and plasma proteins. Arteriolar vasoconstriction is followed by adhesion and aggregation at blood vessel injury sites (primary hemostasis). The extrinsic pathway of blood coagulation is commenced when blood is exposed to tissue factor (Secondary hemostasis). Permanent plug formation includes fibrin deposition, which restricted by mechanisms of the natural anticoagulant system. Ultimately, fibrin is consumed by the fibrinolytic system, the key components of which are plasminogen and tissue-type plasminogen activator (tPA).

5 Blood Group Antigens and Antibodies

Most blood group antigens are glycoproteins, and their specificity is mostly defined by the oligosaccharide chain (e.g., ABO) or protein sequence (e.g., MN, Kell, Duffy, Kidd, etc.). Each blood group system denotes either a single gene or a compilation of closely linked homologous genes. The 36 human blood group system genes have been determined, sequenced, and polymorphisms are known. Blood group antigens are conventionally tested by hemagglutination methods, the tube technique being the gold standard for many years. High throughput and various antigen/antibody testing methods are available. Limitations of serology techniques in recently transfused patients where both donor and patient red cells co-exist or unavailability of some typing reagents have cemented the way for molecular blood grouping.

6 Blood and Blood Components

6.1 Whole Blood

A blood donor donates whole blood which can be processed into different. Whole blood contains 350 mL/450 mL ± 10% of donor's blood with anticoagulant solution. Hematocrit of whole blood is 30–40%. Stored whole blood has nonfunctional platelets and absence of labile coagulation factors. The ability to prepare blood components is advantageous as it allows optimal survival of each constituent and allows specific blood component to be transfused according to the patient requirement. Constant supply of blood components adds to the blood inventory.

6.2 Packed Red Blood Cell (pRBC)

Packed red blood cells (pRBC) are prepared by removing maximum plasma from a unit of whole blood. Red cells settle in the lower portion of bag due to the sedimentation or centrifugation owing to higher specific gravity while the plasma is transferred into a satellite bag. Red cells with additive (Adsol or SAG-M) have hematocrit of 50–60%, minimum plasma and buffy coat (leukocytes and platelets).

6.3 Platelet Concentrates

Platelet concentrate prepared from whole blood is called random donor platelets (RDP) and is stored with agitation at room temperature (20–24 °C) within 6–8 h of collection. It is prepared using any of the following two methods:

(a) By using CPD-A1/CPD-ADSOL or SAG-M triple or quadruple blood bags and refrigerated centrifuge, also known as the platelet-rich plasma (PRP) method.
(b) By buffy coat removal method using blood collection bags (top and bottom) and automated component extractors.

6.4 Fresh Frozen Plasma (FFP)

FFP is plasma prepared from a single donor either by whole blood donation or by plasmapheresis and rapidly frozen within 6–8 h of collection. It contains all coagulation factors and care must ensure to preserve their activity during collection of blood, freezing, and thawing. One unit of factor activity is the amount present in 1 mL of fresh, average normal plasma with one tenth part citrate anticoagulant.

6.5 Cryoprecipitate

Cryoprecipitate is the insoluble portion of plasma remaining after thawing the fresh frozen under controlled conditions. Cryoprecipitate is reconstituted before issue by placing in an overwrap in a 37 °C water bath until the cryoprecipitate has dissolved. Cryoprecipitate should be resuspended thoroughly by gentle massaging. Once thawed, cryoprecipitate should be transfused within 4 h and should not be refrozen.

6.6 Granulocyte Concentrate

Granulocytes for transfusion can be from buffy coat prepared during whole blood separation into components or granulocytes collected by apheresis technology. Granulocytes are transfused to patients with severe neutropenia unresponsive to antibiotics.

6.7 Components Collected by Apheresis Technology

1. **Single Donor Platelets (SDP):**

   Platelets obtained from a single donor by plateletpheresis procedure (removal of platelets from a donor with return of remaining blood components, i.e. red cells, white cells, and plasma) is called single donor platelets (SDP). One SDP is equivalent to platelets obtained from five to six whole blood donations. Patients transfused with SDP are exposed to a smaller number of donors thus preventing the chances of refractoriness to a great extent.

2. **Granulocytes concentrate:**

   Apheresis allows selective collection of a comparatively higher dose of granulocytes than would be found in whole blood with the added advantage for the donor of marginal red cell loss. Minimum yield of granulocyte collected by apheresis must be 1×10^{10} granulocytes/unit.
3. **Source plasma:**

   Source plasma is plasma collected from healthy, voluntary donors by a process called plasmapheresis and is used for further manufacturing into plasma-derived products (fractionation).

7 Modifications of Blood Components

7.1 Leukoreduction

Different methods applied for leukocyte removal are red cell washing, buffy coat removal, use of leukocyte filters, freezing, and deglycerolization of red cells and blood component collection by the apheresis technique. Among all these methods, use of third-generation leukocyte filters and apheresis techniques are most efficient to achieve quality standards. Leukoreduction helps in reduction in febrile nonhemolytic transfusion reaction (FNHTR), HLA alloimmunization and platelet refractoriness, CMV transmission risk, TRALI, TRIM, etc.

7.2 Irradiation

Irradiated blood components prevents transfusion associated graft versus host disease (TA-GvHD), which is a rare but commonly fatal complication of transfusion of cellular blood components. The mechanism is engraftment, proliferation, and mediation of a cellular immune response by the donor T-cells against host tissues, resulting in harm to skin, liver, gastrointestinal tract, and bone marrow [9]. TA-GVHD usually occurs in immunocompromised patients but can also occur in immunocompetent recipients or patients who may have only a mild immunodeficiency due to transfusion of allogeneic immunocompetent T-lymphocytes.

7.3 Washing

Washing of red cells or platelets eliminates 70–95% of leukocytes with an associated loss of 15–20 mL of red cells. It helps in removal of plasma proteins and microaggregates [10]. Washing is indicated in patients with frequent episodes of FNHTRs and allergic urticarial reactions, patients having developed antibodies to plasma proteins, IgA-deficient patients who has anti-IgA, patients with paroxysmal noctural hemglobiuria (PNH) sensitive to complement.

7.4 Pathogen Reduction

Pathogen reduction technology (PRT) has been established to improve blood safety. The principle of current pathogen reduction strategies is based on modifying DNA or RNA templates and making them unavailable to DNA or RNA polymerase. Various platforms of pathogen reduction include treatment with psoralens, alkylating compounds, riboflavin, methylene blue, and solvent–detergent (SD). Pathogen reduction systems have been devised for RBC, plasma, and platelets and is found to be effective for a variety of pathogens including lipid-enveloped and nonenveloped viruses, bacteria, and parasites [11]. The methods used should remove or inactivate pathogens, including emerging ones, with maintaining the function and shelf life of the blood components. In addition, any chemicals used, and the resulting product must be demonstrated as nontoxic and nonimmunogenic.

8 Special Considerations in Oncology Patients

8.1 Pretransfusion Testing Issues in Oncology Patients

- **Issues related to blood grouping:**

  Oncology patients can pose problem during blood grouping due to underlying disease condition, immunosuppression, chemotherapy, ABO incompatible transplant, etc. Table 1 discusses about the different types of discrepancies and methods to resolve it.
- **Alloimmunization in Oncology patients:**

  Red cell alloimmunization is a late complication of blood transfusions affecting 8–12% of all recipients [13]. The alloimmunization percentage increases considerably if patients are multiply transfused like with thalassemia, sickle cell anemia, leukemia, myelodysplastic syndrome, etc. But there is low incidence of alloimmunization of oncology patients due to the immunosuppressive character of chemotherapy and radiation therapy.
- **Antibody screening and identification in oncology:**

  In patients with antibody screen positive, antibody identification by cell panel should be performed. The pattern of antigen expression should be diverse so that it will be feasible to distinguish different antibodies and should include homozygous expression of Rh, Duffy, Kidd, and MNSs antigens. Phenotype matched compatible blood should be provided in antibody positive cases.
- **Antibody titer:**

  Once an antibody is identified, it is occasionally useful to know the antibody titer that is present and antibody titration can help determine antibody concentration levels. Twofold serial dilutions of serum containing the anti-

Table 1 Types of grouping discrepancies [12]

Type of grouping discrepancy	Causes	Resolution
Type 1 (Missing antibody)	• Patients with a leukemia or lymphoma • Patients using immunosuppressive drugs with hypogammaglobulinemia • Patients with bone marrow or stem cell transplantations (patients develop hypogammaglobulinemia and start producing a different RBC population from that of the transplanted stem cells)	• Obtaining proper history • Enhance weak reaction in the serum • Increasing serum:cell ratio • Lower temperature of testing/incubation at 4 °C for longer time
Type 2 (Missing antigen)	• Subgroups of A (or B) may be present • Leukemias may lead to weakening of A or B antigens • Hodgkin's disease • The "acquired B" phenomenon is most often associated with diseases of the digestive tract (e.g., colon carcinoma) • Chimerism – Blood transfusions (e.g., group O red cells given to an A or B patient) – Transplanted bone marrows or peripheral blood stem cells of a different ABO blood group	• Increase cell:serum ratio • Increase incubation time at room temperature for >30 min • Incubate at 4 °C for longer time (15–30 min)
Type 3 (Rouleaux formation)	• Elevated levels of globulin due to certain disease conditions such as multiple myeloma, Waldenström's macroglobulinemia, other plasma cell dyscrasias, and certain moderately advanced cases of Hodgkin's lymphomas • Elevated levels of fibrinogen • Plasma expanders such as dextran and gelofusin used in cases of massive transfusions	• Washing patient's RBCs multiple times with saline • Performing saline replacement technique. (removed serum is replaced with equal volumes of saline. In true agglutination, RBC clumping will persists after the addition of saline)
Type 4 (Miscellaneous)	• Cold reactive autoantibodies in which RBCs are heavily coated with antibody which led to spontaneous agglutination, independent of the specificity of the reagent antibody • Patient has circulating RBCs of more than one ABO group due to RBC transfusion or marrow/stem cell transplant • Irregular/unexpected auto/allo antibodies	• The patient's RBCs can be incubated at 37 °C for a brief period, then washed three times with saline at 37 °C and retyped • The patient's RBCs can be treated with 0.01 M dithiothreitol (DTT) to disperse IgM-related agglutination • As for the serum, the reagent RBCs and serum can be warmed to 37 °C, mixed, tested, and read at 37 °C and can be converted to the antihuman globulin phase if necessary

body are tested against RBCs suspension that possesses the target antigen. Antibody titer plays an important role in selection of blood products in HSCT patients.

- **AIHA in Oncology:**

  In the case of AIHA, autoantibodies directed against the patient's own red blood cells cause hastened red cell destruction. AIHA can be seen in malignancies like leukemia, lymphoma, ovarian tumors, B-cell neoplasms, etc. These patients majorly have warm antibodies reacting at AHG phase. In case of presence of autoantibodies and alloantibodies, adsorption techniques should be used. autoadsorption, homologous adsorption, and differential adsorption are various techniques of adsorption.

- **Chimerism:**

  The presence of two cell populations in an individual is termed as chimerism. It is observed in transplanted bone marrows or peripheral blood stem cells of a different ABO blood group [14]. Chimerism results are typically mixed field. Persistent chimerism after blood transfusion may lead to development of TAGVHD in the recipient.

9 Transfusion in Oncology Patients

- **Packed red cells:**

  The objective of red cell transfusion is same as that for general patients—to increase oxygen carrying capacity of blood. There are no evidence-based guidelines that suggest transfusion trigger in oncology patients. Therefore, oncology patients must be transfused for symptomatic anemia or at predetermined hemoglobin levels as decided by hospital's transfusion policy. For most oncology patients, no special consideration is required for appropriate selection of ABO group for RBC units. However, the choice of appropriate ABO group becomes difficult in ABO mismatch allogenic hematopoietic stem cell transplant (HSCT). For major ABO-incompatible stem cell recipients, recipient type RBCs are provided until there are no detectable incompatible antibodies and the direct antiglobulin test (DAT) is negative. Any plasma containing component (FFP and platelets) should be donor type, to prevent passive transfer of incompatible A and B antibodies.

For minor ABO-incompatible marrow transplants, RBCs should be donors' type, and plasma components should be recipient type until recipient RBCs are no longer detected. For transplants that are bidirectional (both major and minor ABO-incompatible), RBCs should be group O and plasma components should be of group AB.

- **Platelets:**

  Platelet transfusion is a first-line therapy for acute bleeding in patients with thrombocytopenia or those receiving antiplatelet medication. In earlier times, 1990s, the target for routine bleeding prophylaxis was to keep platelet counts greater than 20,000/μL. However, recent trials have demonstrated that spontaneous hemorrhage is unlikely; even with platelet counts as low as 5000–10,000/μL. In addition, patients transfused under more stringent guidelines have shown no change in morbidity and significantly use fewer blood components, thereby reducing the risks of chronic transfusion exposure and thus platelet refractoriness. Although ABO matched platelet transfusions are preferred, ABO mismatched platelets can be given. However, the use of ABO-mismatched platelets in oncology patients can result in reduced therapeutic benefit due to platelet refractoriness.

- **Fresh frozen plasma:**

  The indications for transfusion of plasma and plasma-derived components, such as cryoprecipitated antihemophilic factor (AHF), are similar in oncology and general patient populations. No special consideration is offered to the selection of ABO group for plasma or cryoprecipitate if the unit is ABO identical/compatible with the recipient. Donor and recipient Rh types are not a considered for plasma or cryoprecipitate transfusion. For patients who have undergone allogeneic HSCT, the selection of ABO group plasma should be based upon consideration of major and minor mismatches as mentioned earlier.

- **Granulocytes concentrates:**

  Granulocyte transfusions are required in oncology patients with severe neutropenia to treat life-threatening infections with antibiotic resistance [15]. The decision to initiate granulocyte transfusion usually arises in patients with severe neutropenia or failure to respond to antibiotics with a reasonable chance at sustainable marrow recovery after resolution of the underlying infection.

10 Transfusion Reactions

Any transfusion-related adverse event that occurs during or after the transfusion of whole blood, blood components, or human-derived plasma components is defined as transfusion reaction. They are also classified according to the time interval between transfusion and the presentation of adverse effects (Fig. 1).

An **acute transfusion reaction is** one with signs or symptoms presenting during or within 24 h of transfusion while the one presenting after 24 h of transfusion is defined as a **delayed transfusion reaction**. Transfusion reactions once recognized should be immediately stopped and reported to the Department of Transfusion Medicine. Management of transfusion reactions is discussed in Table 2.

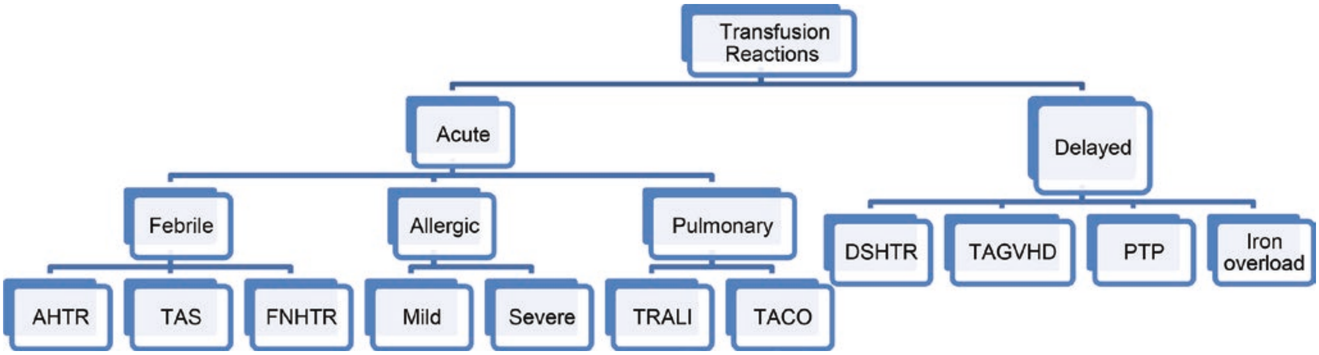

Fig. 1 Classification of transfusion reactions

Table 2 Management of transfusion reactions

Sr. No	Reaction	Treatment
1	Acute Immune Hemolytic Transfusion Reaction (AHTR)	Stop the transfusion, maintain vascular access, maintain blood pressure, renal blood flow, and treat DIC if present
2	Acute non-immune hemolytic transfusion reaction (ANIHTR)	Stop the transfusion, maintain vascular access, Maintain renal blood flow
3	Transfusion-associated sepsis (TAS)	Stop the transfusion, maintain vascular access, Consider initial broad-spectrum antibiotic treatment
4	Febrile nonhemolytic transfusion reaction (FNHTR)	Treat with antipyretics, for rigors treat with meperidine
5	Allergic, Mild	Temporarily stop the transfusion, treat with antihistamines and if symptoms improve restart transfusion
6	Allergic, Severe	Stop the transfusion, maintain vascular access, treat with subcutaneous epinephrine, maintain blood pressure, provide respiratory support
7	Transfusion-related acute lung injury (TRALI)	Stop the transfusion, maintain vascular access, supplemental oxygen, mechanical ventilation
8	Transfusion-associated cardiac overload (TACO)	Upright posture, supplemental oxygen, diuresis
9	Delayed serologic hemolytic transfusion reaction (DSHTR)	As needed transfuse antigen negative, AHG cross-matched compatible PRBC
10	Delayed hemolytic transfusion reaction (DHTR)	As needed transfuse antigen negative, AHG cross-matched compatible red cells
11	TA-GVHD	Supportive treatment with Immunosuppressive agents and Immunomodulators
12	Post transfusion purpura (PTP)	Intravenous immunoglobulin
13	Iron overload	Use of iron-chelating agents

11 Conclusion

Transfusion support is a crucial therapy for patients with hemato-oncology disorders. However, their immunosuppressed state and repeated exposure to transfusion; they are often at more risk for transfusion reactions. Compared to general patient populations, oncology patients are at increased risk for certain transfusion-transmitted diseases, red cell and platelet alloimmunization, TA-GVHD, and immunomodulation. In addition, HSCT patients present distinct challenges for transfusion support as they require particular evaluation for potential ABO incompatibility. Proper selection of blood components and modification if required is therefore necessary to provide appropriate transfusion support to these patients. Considerable advances have been made in transfusion services, including sensitive donor testing and alternatives to blood component therapy, which will continue to improve transfusion safety for oncology patients.

1 History of Palliative Care in India

In 1986, Dr. Luzito D'Souza, a surgical oncologist, established the first hospice called Shanti Avedana in Mumbai, which was supported by dedicated nuns from the Sisters of The Holy Cross. In late 1980s, the initial cancer palliative care services were provided through Tata Memorial Centre. Then, patients with cancer having severe pain were prescribed a tablet called A and O (aspirin and opium). It was manufactured by Haffkine Institute, Mumbai [1]. In 1993, The Pain and Palliative Care Society (PPCS) at Calicut Kerala started home-based palliative care services. It evolved into neighbourhood network in palliative care (NNPC) program a community-led service capable of providing home-based palliative care to all those in need. This program facilitated enormous social mobilization, something that was possible in the socially conscious State of Kerala [2]. In rural areas, the community owned units were set up with the help of the PPCS. The Indian Cancer Society a public charitable trust along with Rotary Bangalore Indiranagar was instrumental in setting up a modern hospice in Bangalore called *Karunashraya* in 1994. In 2010, the palliative care was recognised as a medical subspecialty by the Medical Council of India (MCI). The Certificate Course in Essentials of Palliative Care was started by the Indian Association of Palliative Care in 2007 and The National Fellowship in Palliative Medicine (NFPM) a post-graduate training program in palliative medicine for medical professionals in India started in 2004. In 2012, the Tata Memorial Hospital Mumbai started the first specialist Palliative Medicine training [3]. The *Indian Journal of Palliative Care* (IJPC) a peer-reviewed journal, published four times a year by the Indian Association of Palliative Care. It came into existence in 1995, and it is online since 2007.

2 Palliative Care Need in India

In India, palliative care need is estimated as 175–275 per 100,000 population. India is classified under high palliative care requirement region of the world. Around 70–140 per 100,000 population in India with cancer require palliative care and the rest needing palliative care have progressive non-malignant conditions and HIV/AIDS [4].

More than one million new cancer cases are diagnosed each year in India and with over 80% present with stage III and stage IV diagnosis [5]. More than two-thirds of them are often incurable at the time of presentation and are only candidates for palliative care [6]. Besides these significant numbers of patients who receive treatment for cancer recur, and it is often not amenable to effective cancer directed treatment. About 80% patients with advanced cancer experience moderate to severe pain due to inequitable access to essential pain relief medicines [7]. Hence, palliative care intervention and attention to pain management are warranted early in the course of cancer treatment [8].

A population-based study conducted in a large city of India showed that most people preferred to die at home [9]. In an Indian setting, home-based palliative care might be a cost effective, relevant and practical option [10]. Patients often receive high-cost inappropriate medical interventions at end of life, due to lack of palliative care provision. It often drains the resources of patients and family [11]. Significant numbers of discharges against medical advice (DAMA) from the Indian ICUs are often due to high cost and unavailability of appropriate care at end of life [12]. Unilateral DAMAs preclude patients from receiving care at end of life. The current health spending in India is 4% of the GDP, and there are limited allocated budgetary provisions for palliative care. A significant proportion of the Indian population spend out of pocket for their health-related expenses leading to millions of families are becoming poorer every year due to rising health-related expenditures and most of these expenses are related to treatment during end of life. A universal access to palliative care might avoid this [13].

3 Principles of Palliative Care

Palliative care aims to better the quality of life of patients and their families met with the problems associated with an illness that might limit or alter the course of their lives. It is the goal is to prevent and relieve suffering through prompt recognition, assessment and treatment of physical symptoms, psychosocial issues and spiritual distress.

Palliative care

- Provides symptom management and relief of distress
- Facilitates natural death and acknowledges that dying as a normal process
- Intends neither to accelerate or defer death
- Embeds the emotional and spiritual aspects of care
- Enables assistance to patients to live as actively as possible
- Facilitates reinforcement to the caregivers during the illness and bereavement
- Approach to care is through a multidisciplinary team
- Betters quality of life and positively impacts the illness journey
- Is appropriate to be initiated during initial stages of illness alongside treatment directed at disease management

According to the American Society for Clinical Oncology (ASCO), the palliative care should be integrated with standard cancer care early in the course of treatment for patients with locally advanced disease, metastatic spread or with a high symptom burden.

- Palliative care referral should be made within 8 weeks of diagnosis of metastatic illness
- Palliative care services should be integrated early in both ambulatory and inpatient setting concurrently with active treatment [5, 14].

4 Symptom Management

It is important not only to assess common symptoms but also their severity. The most commonly used scale is the Edmonton Symptom Assessment Scale (ESAS) [15]. Symptom management in palliative care require accurate and meticulous assessment, assessing and addressing non-physical as well as physical issues, using different approaches to manage difficult to control symptoms, weighing risk versus benefit assessments when side effects of therapy occur, communication to the patients and their families, using a multidisciplinary approach and continued reassessment.

The principles of EEMAA facilitates excellent symptom control, which is a critical component of effective palliative care and is based on the

- Evaluation—diagnosis of each symptom before treatment
- Explanation—to the patient before treatment

- Management—individualised treatment
- Monitoring—continuing review of the impact of treatment
- Attention to detail—no unwarranted assumptions

Adhering to such a systematic approach, helps not only in better symptom control but also increases compliance and holistic care.

Generally, pain in patients with cancer, especially in a palliative care setting, is described as a multi-faceted experience where sensory, affective, cognitive and behaviour are its four key facets. Often these patients suffer moderate to severe pain [16]. It is often present at multiple sites exhibiting diversity in intensity and has a complex underlying pathophysiology and clinical presentation [17]. The sensory component of pain manifests its affective dimension in the form anxiety, low mood and distress [17]. The person experiencing the pain cognises it as unpleasant experience, adverse emotions and might influence the entire personhood of the individual [18]. They could present with certain behavioural manifestations like abnormal posture, curtailment of activities of daily living, isolation from society, avoiding treatment and not complying with the prescription and impacting the pain relief and holistic care of the patient [19]. There is a significant difference in cancer pain management in an outpatient setting, home setting, hospital setting and hospice setting. These differences are further discussed below.

4.1 Guidelines for Cancer Pain Management in Ambulatory Palliative Care Setting

In an outpatient palliative care setting, the algorithm often used is the analgesic step ladder provided by the World Health Organization (WHO). It is founded on the intensity of pain (mild, moderate or severe) described by the patients and recorded using a numerical rating scale. Mild pain is often treated using non-opioid preparations like non-steroidal anti-inflammatory drugs (NSAIDs) or paracetamol (acetaminophen). Moderate pain is managed using weak opioids like Codeine, Tramadol and Tapentadol either singularly or along with non-opioids and adjuvant analgesic. Severe pain needs strong opioids like Morphine, Fentanyl and Methadone used by itself or along-side a non-opioid or adjuvant analgesic [20, 21]. The analgesic ladder by WHO provides easy applicable sequential steps for specialists and generalists pain management. In a chronic pain setting, it might avoid misuse of opioids and might lessen the apprehension of addiction and legal action. It can be applied across the world in any setting and might be of great value in the developing countries where there is paucity of pain specialists. Research has shown that stepladder approach enabled excellent pain control for a significant duration in vast majority of patients [22]. Up to 76% of them might achieve excellent pain control with this algorithm; and 12% of them got satisfactory betterment and 12% had no benefit [23].

4.2 Guidelines for Cancer Pain Management in Acute Inpatient Palliative Care Setting

Some with cancer pain need hospitalisation in an acute inpatient palliative care unit for severe pain. In an outpatient and a home setting, fast opioid titration, using complex drugs like Methadone, managing pain crisis, neuromodulation of and interventional techniques are not feasible [24]. Quick oral opioid dose adjustments alongside adjuvants are recommended for uncontrolled pain. Interventions meant to modify the amendable cause of cancer pain is achieved using radiation therapy, physical medicine, correcting high calcium, etc., which is only possible during the inpatient admission. The crisis pain is managed using parenteral opioid trial followed by continuous opioid infusion [25]. The opioid infusions are changed to oral and transdermal medications when adequate pain relief is achieved. The patients with crisis nerve-related pain get intravenous lignocaine or ketamine boluses followed by continuous doses until neuromodulation is accomplished. Inpatient admission is needed to adjust the doses of drugs like methadone used for mixed nociceptive neuropathic cancer pain [26]. Interventional pain management procedures are used in the setting of cancer pain, where adequate pain relief is not achieved with strong opioids [27].

4.3 Guidelines for Cancer Pain Management in Home-Based Palliative Care Setting

In a home-based care setting, the nurses and primary physicians assess cancer pain with restricted contribution from the specialist physicians. These evaluations are intermittently done, which leads to poorly controlled pain, insomnia, anxiety, low mood, frequent hospitalisations, high cost and diminished quality of life [28]. They are prone to polypharmacy, excessive over the counter unprescribed medication use and detrimental side effects of the analgesics [29].

They could be managed in similar lines to outpatients using the algorithm of analgesic step ladder [21]. Furthermore, they should get pain self-reporting guide and pain journals for detailing pain scores and other pain-related specifics. They should also receive medication book for recording daily use of background painkillers and breakthrough dosages. It is also suggested to provide pre-emptive analgesic instructions in certain cancer patients in expectation of rapid change in patient's pain and circumstance [30]. They are directed to get the analgesic drugs from the hospitals or general practitioners before they expend their medicines. They are also connected to local dispensary and their GPs to guarantee sufficient continuous supply of analgesics.

4.4 Guidelines for Cancer Pain Management in Hospice and End-of-Life Care Patients

Pain is often a unseen cause of suffering and distress during end of life as patients at their end of life might not be able to articulate pain or have a level of cognitive loss that could hinder pain expression [31]. Misconstructions about pain at end of life, suitability and adverse effects of analgesics, pain underreporting and intricate presentation of pain at end of life could constraint use of analgesics [32]. Doctors often lack proficiencies in recognizing and evaluating pain in patients at end of life with cognitive loss. They also lack skills in deciding suitable analgesics, route, adjustment and using breakthrough analgesics [33]. Patients during their end-of-life face several symptoms at end of life. The quality of life and death is an aggregate result of symptom control and managing psychosocial issues [34]. The research has shown that pain control at end of life is lacking, and unmitigated pain could corrode the self-worth and well-being at end of life [35].

In a cancer setting, for patients at end of life, the pain should be evaluated at least daily. The pain must be expected, and a pre-emptive treatment ought to be offered to all the patients in a hospice or in a hospital for end-of-life care. Besides, doctors should be skilled in evaluating patients with pain who are incapable of articulating pain or has cognitive loss [36]. The doctors should guarantee access and obtainability of all drugs needed for pain management. Painkillers and their doses must be based on careful appraisal of patient's pain. Their doses should be proportional to patient's pain and response to medications should be regularly reviewed. Furthermore, even when patient is in end of life, no attempt must be made to give a higher than necessary dose or incorrect quantity. The PRN (SOS) orders ought to be scripted up to cover recurrent pain and breakthrough pain. In the end-of-life situation, the PRN doses must be used freely used and quick modification of doses of background (round the clock) prescription should be done. The route of painkillers provision at end of life might need to be altered to subcutaneous or intravenous route if the patient cannot take the drugs orally [37]. The palliative sedation must be contemplated at end of life if pain becomes intractable to standard analgesics [38].

Nausea and vomiting are common symptoms experienced by patients with advancing cancer. It may be due to anticancer therapy, drugs or bowel obstruction. It is important to identify the receptor which is being stimulated, so as to treat appropriately. Some general guidelines are to reverse the causes where feasible, check plasma levels of creatinine, digoxin, calcium and rationale prescribing of the drug according to the receptor involved by the inciting cause.

Constipation is common in patients with advanced cancer due to prolonged immobility in patients with advancing cancers, loss of appetite with dehydration and lack of privacy to use toilet and drugs. The non-drug measures like increasing oral intake, encouraging fluids, mobilizing patient where feasible and providing privacy and access to toilet. Generally, a combination of softeners and stimulants are the common pharmacological treatment used in patients with advanced cancer.

Anorexia is the loss of appetite or desire to eat. Cachexia is an involuntary, ongoing loss of bodyweight (>5%) in the last 1–2 months. Could be accompanied by other factors like anorexia, muscle strength decline or inflammation. In patients with significant fluid retention, large tumour mass or obesity, significant muscle wasting may occur in the absence of weight loss. Corticosteroids and progestational agents are often used to help anorexia.

Fatigue is easy tiring and reduced capacity to maintain performance. It is often accompanied by generalised weakness, sensation of difficulty in initiating a certain activity, mental fatigue, defined as the presence of impaired mental concentration, loss of memory and emotional lability. Along with corticosteroids and progestational agents, methylphenidate and modafinil help patients with cancer-associated fatigue.

Breathlessness is a common in patients with advanced malignancy. It may be due to primary carcinoma of lung or mediastinal tumours causing airway obstruction, lymphangitis carcinomatosis, lung metastasis, pleural or pericardial effusion or systemic causes like anaemia. These patients are managed by correcting the cause and low-dose morphine for chronic refractory breathlessness.

Delirium is a common symptom encountered in patients with advanced disease, especially when entering terminal phase. It is distressing both to patients and family members. Management involves reversing the causes like dehydration, hypercalcaemia, bladder or bowel distension, maximising non pharmacological interventions like safe environment, quiet room, familiar professional staff and using typical anti-psychotics like haloperidol or atypical anti-psychotics like quetiapine, risperidone or olanzapine.

5 Psychosocial Aspects of Palliative Care

A comprehensive psychological assessment is integral in the management plan of patients with advanced cancer. The assessment process has to be conducted with empathy, maintaining privacy and confidentiality along with unconditional positive regard and acceptance. Factors to be assessed include patient's perception or awareness of diagnosis and prognosis, current mood symptoms like depression or anxiety, demoralization, presence of sleep and appetite disturbances, fatigue and sense of well-being [39, 40].

The person's journey through different phases of life, significant life events, presence of stressors other than advanced life-limiting illness and sources of interpersonal support are to be noted. Appreciating the person's illness beliefs, illness behaviour and coping styles will help in developing a comprehensive management plan. The presence of personal or family pre-existing psychological issues/functioning or psychiatric disorders are essential to note. The psychological assessment, in any setting—outpatient clinic, inpatient wards or home/respite/hospice care, includes communication related issues like awareness and awareness of diagnosis and prognosis, presence of collusion and denial. Psychological issues of loss, grief, role changes, sleep disturbances, fatigue and quality of life have to be explored. Impact on mood, and presence of depression, anxiety and post-traumatic stress have to be looked for. Various diagnostic instruments can/should be used for assessment of important clinical disorders like depression, anxiety and delirium, which are common in palliative and hospice care settings. Various tools can be used for, e.g. Distress Thermometer and Problem Check List (DT/PCL), Hospital Anxiety and Depression Scale (HADS), Edmonton Symptom Assessment Scale (ESAS), Hamilton Depression Rating Scale (HDRS), Beck Depression Inventory (BDI), Spiritual Needs Inventory, Beliefs and Values Scale and Palliative Outcome Scale (POS) [4, 6]. Screening and assessment for delirium on can be done by Memorial Delirium Assessment Scale (MDAS) and Nurse Delirium Scale (NDS) [41].

It is equally important to assess the caregivers' quality of life as it has been reported that the caregiving burden can increase as the patient's disease progresses. The mental health and coping of caregivers are essential components of the comprehensive assessment. Family caregivers can experience even greater distress than that of their patients. Family functioning and relationship are predictors of complicated bereavement process. A thorough mental state examination is done to help in identifying affective and anxiety disorders, delirium and cognitive deficits. Individual and family coping, sources of interpersonal support and family cohesion or conflicts are recognized in a well conducted and detailed patient and caregiver interview [42].

Holistic care integrates needs of family and patient as a unit. Often the family has been decimated with the expenses of the cancer therapy. The social worker needs to assess economic status of family, home environment along with social support systems. The economic, medical, nursing and educational needs of the family are assessed.

Spiritual distress assessment has these primary objectives:

- Develop a therapeutic bond with the patient in a clinical setting
- Recognise spiritual issues and confirm, explicate or arrive at a spiritual diagnosis
- Formulate a spiritual care plan that can be shared with the team

For assessment, the FICA scale has proved to be the most useful.

F—Faith and belief—Do you have spiritual beliefs that help you cope with stress?
I—Importance: "What importance does your spirituality have in your life?"
C—Community: "Are you part of a spiritual or religious community? Is this of support to you, and how?"
A—Address: "How would you like me, your health care provider, to address these issues in your health care?"

6 Ethics of Palliative Care

This is one of the most imperative yet difficult areas in palliative care. The four major principles that govern ethics are autonomy, non-maleficence, beneficence and justice. During this time of suffering, conflict arises mainly due to lack of communication between patient's family and professionals. Given the finality of the life-limiting illness; if patient autonomy is respected and patient has a chance at 'decision making' early in the trajectory of an advancing cancer, should there be any conflict? If 'quality of life' is paramount, rather than prolonging unnecessary suffering, then can allowing a patient to die in a hospital or at home, surrounded by loved ones, be considered as beneficence rather than maleficence? This also mirrors the Hippocratic Oath of always working in the best interest of the patient. Withholding unnecessary interventions or withdrawing of the same, when they are not working, is understanding the concept of medical futility. This could hold true for mechanical ventilation, artificial nutrition and hydration, CPR and many other issues. Conflicts arise when patients are referred late in the trajectory of illness, when next of kin is not properly identified, the patient is not mentally competent etc. Constant, consistent and competent communication should be able to resolve conflicts. Physicians should have recourse to other experts in the field, hospital administrators and ethics committees, lastly the courts, to resolve ethical dilemmas and conflicts; this unfortunately can lead to waste of precious time while patient is in the terminal phase in an ICU. It is also incumbent on doctors to respect other ethical issues like duty to alleviate suffering, respect for individual, utility and human rights.

Respecting patient's right to decision making cannot in any way be construed as euthanasia or physician-assisted suicide; these are deliberate acts to end the life of a patient and palliative care physicians condemn such acts. On 10 March 2018, the Supreme Court of India verdict stated that right to life, including the right to die with dignity is upheld, as part of an individual's constitutional right, under Article 21 of the Indian Constitution. This followed the Mumbai High court judgement on the Right to Die with Dignity petition, regarding Aruna Shanbaug, a nurse who lay in a permanent vegetative state at the KEM hospital for over four decades. The learned judges also stated that an adult conscious human being, is fully entitled to refuse medical treatment and may decide to embrace death in a natural way. This is very much in tune with the 'Principles of Palliative Care'. Moreover, the court accepted the validity of advanced directives where an individual can exercise his/her autonomy on the extent of medical intervention that he/she wishes to allow upon his own body at a future date, when he may not be in a position to specify his medical wishes. This would be needed to be upheld both by medical professionals and the next of kin. However, the downside of this verdict, was in the terminology, i.e. that limitation of such life sustaining treatment be termed as 'passive euthanasia'. This is an inappropriate use of the nomenclature, which does not exist in the medical dictionary. Following this landmark judgment, On 12 March 2018, the Indian Council of Medical Research (ICMR) commission released a report with 25 definitions regarding limitation of life-sustaining treatment and providing palliative care at the end of life. The purpose of this report was to facilitate discussion, preparation of guidelines and framing of laws, relating to the treatment limitation and providing palliative care at end of life. The Ministry of Health and family Welfare, along with ICMR and working on developing an Advanced Directive Health Care form.

7 End-of-Life Care and Bereavement Support

An excellent end-of-life care is a person focussed, tailored view of 'Good Death', which incorporates all features of wide-ranging care of an individual at his or her end of life. It involves (1) pertinency to any individual, any place and any disease; (2) respite from physical, emotional, social, spiritual and existential issues; (3) dying at the favoured place of choice and getting suitable care by a skilled health care provider and (4) general access to palliative care at end of life and each person having access to privacy, serene and dignified death [43–45].

Qualitative research of bereaved family/caregiver suggested that end of life their patients experienced (1) inadequate symptom control; (2) partial health related communication; (3) absence of skilled health care resources to provide end-of-life care; (4) non-existence of rounded care; (5) requests of desired place of death not achieved; (6) detached equipment loaded end-of-life care and (7) delayed palliative care referrals. These were important barriers that hindered quality end-of-life care [46–49].

Research on hospital end-of-life care practices showed that (1) prolongation of disease directed treatments until last weeks of life; (2) needless life-sustaining measures; (3) delayed referral to palliative and supportive care services and (4) absence of advanced care planning and nonexistence of anticipatory directives for end of life. These were the key barriers that hindered quality end-of-life care [50–53].

Quality of Death (QOD) Hospice scale, Quality of death and dying (QODD), Care Quality Commission (CQC) review, family assessment of treatment of end of life (FATE) and quality of end-of-life care and satisfaction with treatment (QUEST) are some of the validated tools that measures gaps in quality end-of-life care. These are intended to gauge views on quality of end-of-life care by qualitative interviewing bereaved family caregivers. Quality of death could also be known by reviewing hospital end-of-life care practices through prospective and retrospective research studies [52, 54–57].

The End-of-Life Care in India Taskforce (ELICIT) is constituted by the IAPC in collaboration with Indian Society of Critical Care Medicine and Indian Academy of Neurology. This team is functional concerning a strong ethical and legal structure for enabling good end-of-life care. The end-of-life care consortium was created after the 2010 quality of death report by Lien foundation to foster and support end-of-life care in India. The important purpose was to develop position statement, policy guidelines, impact policy creators and facilitate end-of-life care knowledge among health care providers and public. In September 2014, a position statement [58] and policy guidelines [59] was published. End-of-life care awareness initiatives were commenced across India with the help of CMEs and Webinars. The association had numerous meetings with the National Accreditation Board of Hospitals (NABH) and was effective in introducing crucial modifications to NABH manual concerning end of end-of-life care. To enable end-of-life care delivery throughout India, a meeting by the International Collaborative on best care of the dying was conducted at the Bangalore Baptist Hospital. Bengaluru. Several participants from many organizations involved in palliative care across India, attended the program. The purpose of this program was to propagate information and advance end-of-life care practices across India.

In aftermath of modification of National Accreditation Board of Hospital (NABH) manual, the Quality Council of India invited delegates of Indian Society of Critical Care Medicine (ISCCM) and Indian Association of Palliative Care (IAPC) to offer ideas for restructuring COP 20.0 item of

2011 NABH accreditation manual, which deals with assessing end-of-life care delivered in Indian Hospitals. The delegates of both the associations met the members of quality council of India on 17 July 2015. A form was consequently developed based on IAPC consensus position statement on end-of-life care policy for dying [59], ISCCM and IAPC joint position statement on end-of-life care policy [59] and NABH COP 20.0 items of NABH Manual, 3rd Edition. Professional views of members for both the society/association were pursued and integrated. To offer quality end-of-life care, it is crucial that standards of end-of-life care as endorsed by suitable establishments are applied, and application process is supervised by various national and international accreditation agencies. Therefore, National Accreditation Board for Hospitals (NABH) and Health Care Providers COP 19 of the NABH 2016 document were developed to enable accreditation of hospitals in India. Nevertheless, most often, these guidelines are limited to paper and truthfully end-of-life care practices are never assessed. This is because these accreditors assess presence of a document not its execution or practice. The auditors themselves have a very incomplete understanding of end-of-life care and are do not have the expertise to carry out these audits.

Recently, the Indian Council of Medical Research (ICMR) in collaboration with ISCCM, IAPC and ELICIT has developed the process of creating uniform end-of-life care definitions, which is already published.

8 Paediatric Palliative Care

When children are diagnosed with a life-limiting condition, it is an extremely harrowing situation where contrary to the normal course of life and death, a beloved child is passing on before the parents. The feelings of frustration and helplessness are not only with the parents and siblings but with the team as well.

Common conditions in paediatric palliative care are grouped under four main headings:

1. Life-threatening conditions for which curative treatment may be feasible but can fail, e.g. cancer, organ failure.
2. Conditions were premature death is inevitable but life may be prolonged, e.g. cystic fibrosis.
3. Progressive conditions without curative treatment, e.g. Batten disease.
4. Irreversible but non-progressive conditions where severe disability can lead to premature death, e.g. cerebral palsy.

Unlike cancer, the life of the child suffering from a non-malignant condition could be prolonged, even reaching adulthood. It means many years of support for child, parents, siblings and extended family. The ICPCN estimates that worldwide 20 million children can benefit from palliative care, but access to such services remains an issue.

Some areas in assessment and management unique to children and their families are

Physical
- Age-appropriate clinical assessment (minimal investigations where appropriate)
- Prevention of symptoms whenever feasible
- Use disease-modifying therapy when there will be benefit outweighing toxicity
- Arrange a continuum of care

Psychological and Spiritual
- Age-appropriate assessment and management of psychological and emotional needs
- Counselling—Family as a unit, including siblings

Social
- Identification of financial needs
- Developing social support networks with appropriate referral to other services

Legal
- Identification of legal requirements
- Referral to appropriate legal services
- Documentation of advance directives and patient preferences for care.

8.1 End-of-Life Care

As in adults, the best possible dignity of death should be aimed for whether in an isolated bed in the ward, the home or hospice. Adequate symptom control with essential medication by the appropriate route, surrounded by loved ones. This is best arranged in collaboration with the local GP. A home death would need the arrangement of the death certificate and other formalities.

8.2 Spiritual Care

The essence of paediatric palliative care in India hinges on spirituality. Most people have a firm belief in God and the theory of Karma, which helps in coming to terms with the suffering associated with advancing cancer. The belief that God helps the child to bear the pain and the family the loss when the child is no more; offers a lot of solace to the family. The even more intangible suffering associated with the oft asked question “Why me” by grieving parents about to lose a beloved child is more difficult. While being unable to truly understand having not gone through the trauma ourselves, gentle patient listening with adequate emotional support over a period of time is of some benefit.

8.3 Symptom Management

Largely as in adults. There are certain myths, e.g. babies do not feel pain. These fears need to be allayed and evidence-based medicine practised for effective symptom management. Although many medications are considered not recommended in children, the reality of the situation is that these drugs do not get tested in children. Some drugs are used as 'off label' use after consultation with parents, if no other effective drug is available. Dosage is calculated individually on the BMI or kg body weight. Metabolism of the drugs is quicker in children and sometimes dosages needed to be given more frequently than in adults. Oral route is preferred wherever feasible. Some children have a Hickman or PICC in situ which is useful for continuous medication where oral route is not feasible. S/C route is used rarely and only possible with a syringe driver or pump. IM injections should be used even more rarely.

8.4 Bereavement Support

A vital section of palliative care is provided by all palliative care teams until the next of kin has the ability to move on in life. The grief is felt by 90% of families. Prolonged, delayed or excessive form of depression can have serious effect on life, and prolonged intervention might be necessary. Studies have shown that response too soon by palliative care teams can even be harmful and should be limited for those families manifesting abnormal grief. Right timing of a bereavement support is researched, and there are diverging views in literature [60].

9 Challenges in Delivering Palliative Care in India

At present, there is no national palliative care policy and only two states in India, Maharashtra and Kerala have state palliative care policy. According to 2015 Quality of Death report ranking, in India, the capacity to deliver palliative care is scored as 0.6/100, i.e. only 0.4% of the population in India have access to palliative care. At present in India, there is only availability of one full time practicing specialist palliative care physician per one million population [61].

Access to oral morphine might be a marker of palliative care delivery. Approximately 0.4% of the patients in India have access to oral morphine [62]. In 2008, India used a quantity of morphine adequate for around 40,000 patients experiencing moderate to severe cancer pain [63]. Morphine is encompassed in the National Essential Medicine List. However, its accessibility remains sparse [64]. The morphine and morphine comparable opioid consumption in India at present is <1 mg per capita [65]. Although there was a recent amendment to Narcotic Drugs and Psychotropic Substance Act in 2014, its execution remains challenging [66].

India has a roughly 100 million elderly population currently, which is projected to rise to 324 million by 2050, forming 20% of the whole population. It is anticipated that 60% of elderly patients might have cancer [67]. Surveillance Epidemiology and End Results (SEER) study of the National Cancer Institute in the USA indicates that cancer is 11 times more probable to occur in people over 65 years as matched to their younger counterparts [68]. An ICMR population-based cancer registry report demonstrated that the frequency of cancer patients in India above the age of 60 is expected to touch more than one million by 2021 [69].

The present legal position in India is only limited to passive euthanasia, and there is no well-defined legal framework or policies to support the clinicians on palliative and end-of-life care. Non-existent national palliative care policy and equivocal legal positions are the most important disadvantages to the delivery of efficient palliative care [70].

Clinical Pharmacology in Oncology

Vikram Gota, Manjunath Nookala Krishnamurthy,
Anand Patil, Jyoti Nehra, and Parsshava R. Mehta

Abbreviations

6-MP	6-mercaptopurine
ABW	Actual body weight
AUC	Area under the concentration–time curve
CEA	Cost-effective analysis
CLL	Chronic lymphocytic leukaemia
$C_{\max}$	Maximum plasma drug concentration
CrCl	Creatine clearance
CUA	Cost–utility analysis
DDI	Drug–drug interactions
DPD	Dihydropyrimidine dehydrogenase
ECG	Electrocardiogram
H2A	H_2 receptor antagonist
HRQOL	Health-related quality of life
KDIGO	Kidney Disease: Improving Global Outcomes
MTHFR	Methylenetetrahydrofolate reductase
NSCLC	Non-small cell lung cancer
PD	Pharmacodynamic
PE	Pharmacoeconomics
PK	Pharmacokinetic
pop-PK	Population PK/PD analysis modelling
PPI	Proton pump inhibitors
QALY	Quality adjusted life years
QTc	Corrected QT interval
SrCr	Serum creatinine
TDM	Therapeutic drug monitoring
TKI	Tyrosine kinase inhibitor
TPMT	Thiopurine methyltransferase

1 Introduction to Clinical Pharmacology

Clinical pharmacology deals with the relationship between drugs and individuals and helps in rational prescribing of drugs to treat diseases, alleviate symptoms and prevent adverse effects. Benefits and risks in the form of adverse effects of a drug or undesirable drug interactions should be weighed against each other while prescribing the drugs. Also, the benefits of prescribing a drug should be justified by the cost per unit gain in health metric. As we enter into the era of personalized medicine, the notion 'one size fits all' is gradually replaced by the paradigm of individualized dosing. Thus, the field of modern-day clinical pharmacology draws inspiration from our knowledge and understanding of pharmacokinetics, pharmacodynamics, pharmacogenetics and pharmacoeconomics.

Some important definitions of terms commonly used in clinical pharmacology are provided below:

Clinical pharmacokinetics: Pharmacokinetics deals with 'what body does to the drug' in terms of absorption, distribution, metabolism and excretion. Application of pharmacokinetics in therapeutics is called clinical pharmacokinetics.

Clinical pharmacodynamics: The processes such as receptor binding and chemical interactions by which a drug can affect the physiology, biochemistry and molecular pathways of health and disease is known as clinical pharmacodynamics.

Therapeutic index: It is the ratio of the dose of a drug that causes the therapeutic effect to the dose that causes toxicity. It is also referred to as therapeutic ratio.

Therapeutic window: The dose range across which the therapeutic response is observed without significant toxicity is called the therapeutic window. It is the difference between minimum effective concentrations and minimum toxic concentration.

Clinical toxicology: The branch of clinical pharmacology dealing with the prevention and treatment of adverse effects caused by drugs and toxins is called clinical toxicology.

2 Pharmacokinetics

Pharmacokinetics describes the concentration–time profile of a drug. Important processes involved in pharmacokinetics are absorption, distribution and the two routes of drug elimination—metabolism and elimination. They are known by the acronym ADME. Distribution, metabolism and excretion are sometimes collectively referred to as drug disposition.

2.1 Absorption

The movement of a drug from the site of administration into the bloodstream is called absorption. This process is involved in all routes of administration other than intravenous route. The drug molecules must cross tissue membranes (e.g. subcutaneous tissue, skin, gut epithelium and capillary wall) to enter the blood. The extent to which a drug is absorbed into the systemic circulation is called *bioavailability*.

2.2 Distribution

Distribution is defined as the movement of a drug from one location in the body to another location in a reversible fashion. Following systemic absorption, movement of drug molecules across capillary walls to enter the tissues and subsequently the cells by crossing the cell membrane is essential for pharmacological effects of a drug.

2.3 Metabolism

The process by which drugs are biotransformed from a lipid-soluble form suitable for absorption and distribution to a more water-soluble form that is suitable for excretion is known as metabolism. Metabolism primarily occurs in the liver, gut wall, kidney and skin.

Drug metabolism occurs in two phases:

Phase I—These reactions involve either adding or unmasking a functional group to the drug and thereby making it more polar. Functional groups such as -OH, -NH_2, -SH prepare the drug molecule for phase II reactions described below. Phase 1 reaction usually proceed by oxidation reactions catalysed by members of the cytochrome P450 family of enzymes found in the hepatocytes' smooth endoplasmic reticulum. Majority of products of phase I metabolism are pharmacologically inactive; however, some retain activity to varying degrees and some exhibit activity that the parent drug lacked.

Phase II—The phase I metabolites (or in some cases, unchanged drug) undergo covalent linkage with endogenous substrates such as glucuronide, sulphate, glutathione, acetate and methyl groups to form an inactive compound which is more water soluble and gets excreted easily.

2.4 Elimination

Elimination is an irreversible process by which the drug is removed from the body. Drugs with a low molecular weight that are sufficiently water soluble are eliminated in the urine. Only the unbound concentration of the drug is filtered by the glomeruli and is available for elimination. Drugs with high molecular weight are preferably excreted via the faecal route after conjugation in the liver. Depending on their lipid solubility, certain unchanged drug or metabolites will be reabsorbed and re-enter the blood stream via the portal vein. This recycling between the liver, bile, gut and portal vein is known as *enterohepatic circulation*.

2.5 Concentration–Time Relationship

Usually, following drug administration, absorption and distribution take place relatively faster, and elimination happens at a slower pace. Pharmacokinetic relationship can be described by plotting the plasma drug concentration against time since administration. While majority of the drugs have first-order elimination kinetics (a constant fraction of the substance being removed over time), a small minority exhibit zero-order kinetics (a constant amount of drug is removed over a given time). The concentrations of the drugs that follow first-order kinetics at different time points can be predicted based on their half-life—the time taken for the drug concentration to halve. Furthermore, the relationship between concentration and time varies based on the route of administration too. For example, duration of exposure is longer when a drug is administered intravenously than when it is administered orally.

2.6 Repeated Drug Administration

Drugs are effectively removed from the body within hours or days after administration by metabolism and excretion. To ensure that the drug concentrations at the site of action remains effective, prescribers have to plan repeated drug administration. Quite often, the frequency of dosing, the time taken to achieve steady state concentration, and the time required for the drug to disappear after treatment is stopped will be determined by the pharmacokinetic characteristics of individual drugs. Thus, some drugs with short half-lives have to be administered continuously by intravenous infusion, while others with long half-lives require loading doses to hasten their clinical effects.

2.6.1 Steady State

Steady state concentration is said to be achieved when the dosing rate equals the rate of elimination. Chronic disease situations require the systemic drug levels to reach target steady state levels for maximum safety and efficacy. The time taken for a drug to reach steady state is a function of the elimination half-life of the drug. It takes approximately 5–7 half-lives of the drug to achieve steady state concentrations (Fig. 1).

Maintenance Dose The maintenance doses are calculated in such a way so as to maintain steady state concentrations, i.e. just enough drug is given in so as to replace the drug eliminated in preceding dose. Clearance of the drug is the most important parameter to be considered for maintenance dose.

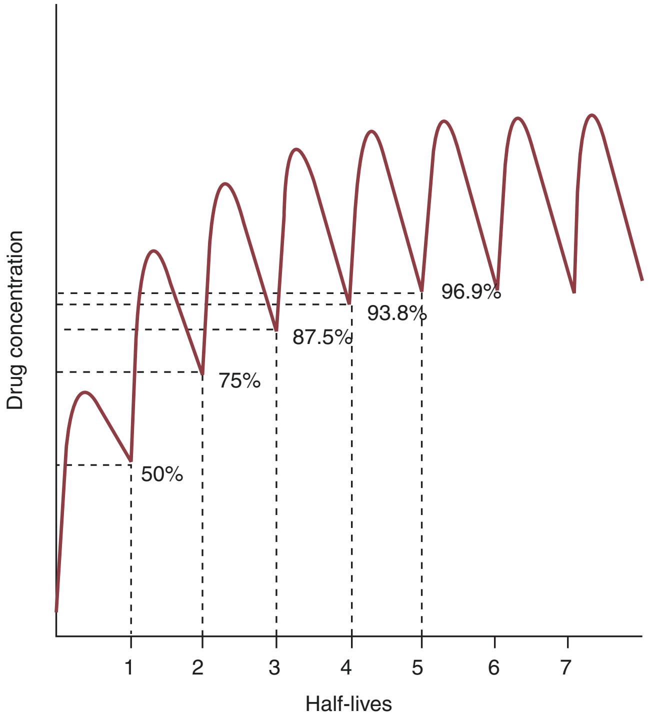

Fig. 1 Steady state: The graph depicts the number of half-lives required to achieve steady state concentration following repeated administration of a drug

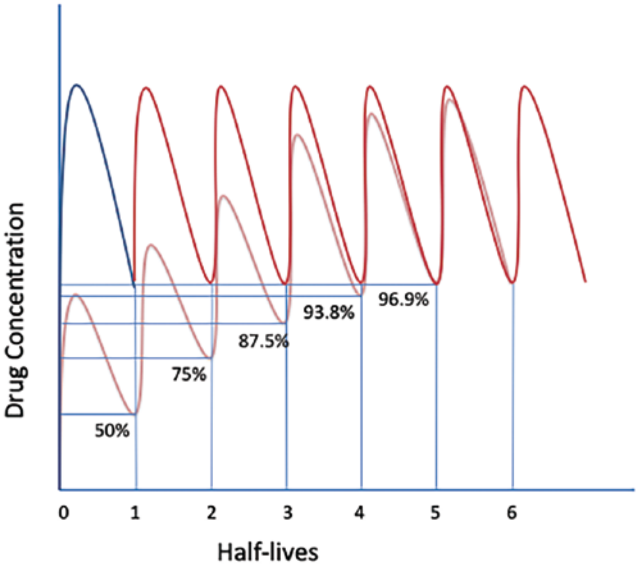

Fig. 2 Loading dose and maintenance dose: The figure demonstrates the importance of loading dose (blue curve) in achieving steady state rapidly. In contrast, it takes 5–6 half-lives to achieve steady state in the absence of a loading dose (red curve). Once achieved, steady state can be maintained using maintenance doses

Drugs which are eliminated rapidly because of short half-life, achieve steady state in a relatively short time. On the other hand, drugs that are eliminated slowly could require days or weeks to achieve steady state. However, if the therapeutic effects are needed quickly (pain relief, antibacterial effect, etc.) and the drug has a long half-life, one can use a loading dose to achieve therapeutic levels on the first dose.

Loading Dose The loading dose rapidly achieves the target concentration necessary to provide the desired therapeutic effect (Fig. 2). The volume of distribution of the drug plays an important role in the calculation of loading dose.

The relationship between the loading dose and volume of distribution (Vd) is given by the equation.

$$\text{Loading dose} = C_{\mathrm{T}} \times \mathrm{Vd}$$

where C_{T} is the target plasma concentration.

The loading dose should be twice the maintenance dose whenever the dosing interval is similar to the half-life of the drug. This is explained by the fact that after one half-life the drug concentration will have dropped by half, thus ‘topping up’ with another maintenance dose will bring it back to the same peak concentration as the loading dose.

3 Pharmacodynamics

Generally, drugs interact with receptors located either on the cell membrane or within the cell and activates them leading to a biological response. The response is proportional to the concentration of the activating drug (the *agonist*). A dose–response curve is used to depict the relationship between the drug dose (or concentration) and its effect [1]. The maximum biological response that a drug can achieve is called *efficacy*, and the amount of the drug required to achieve a response is called *potency* of the drug (Fig. 3).

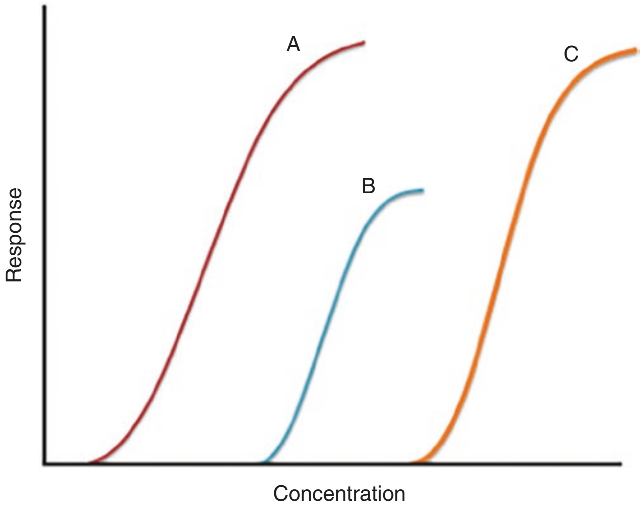

Fig. 3 Potency and efficacy: Concentration–response plots of three drugs A, B and C are shown. Drug B vs. Drug A: A downward and outward shift is seen in the dose–response curve of drug B. This suggest that drug B is less potent and less efficacious compared to drug A. Drug C vs. Drug A: Only an outward shift is seen in the dose–response curve of drug C. This suggest drug C is less potent but equally efficacious as drug A. Drug C vs. Drug B: An outward and upward shift is seen in the dose–response curve of drug C. This suggest drug C is less potent but more efficacious than drug B

4 Interindividual Variability

4.1 Pharmacodynamics

Variation in response to variation in target receptorsin terms of structure and number, receptor coupling mechanisms or a result of physiological changes in target organs resulting from genetic differences, health status or age of the individual. For example, mutations in the kinase domain of epidermal growth factor receptors (e.g. ErbB1-L858R) in some lung cancer patients are known to confer higher affinity and sensitivity to kinase inhibitors such as gefitinib [2].

4.2 Pharmacokinetics

The variations in the drug concentrations achieved by equivalent doses are attributed to various factors which affect the absorption, metabolism and excretion of the drugs. The most important source of such variability in response to a drug is drug metabolism. A high-fat meal corresponds to an 80% increase in the nilotinib levels, the distribution of sorafenib is highly influenced by hypoalbuminemia and variation in cytochrome P450 and ABC transport polymorphism accounts for metabolism of tamoxifen and most other TKIs (sorafenib, gefitinib, imatinib and dasatinib).

4.3 Therapeutic Drug Monitoring (TDM)

TDM entails the measurement and interpretation of drug concentrations in biological fluids in order to individualize patient management. To enhance therapeutic efficacy while minimising unwanted effects, the dose is often modified based on serum/plasma levels. Inter-patient variability in pharmacokinetics of anticancer drugs contributes to the inter-individual differences in response to these drug [3, 4].

Table 1 Drugs for which therapeutic monitoring is indicated in oncology

Drug	Concentration	Need for TDM	Level of evidence
Methotrexate	<0.5–1.0 µmol/L, 48 h after high-dose methotrexate	Methotrexate displays high variability in total body clearance (40–400 mL/min)	Level 2
Busulfan	Target 6 h AUC is 900–1500 µmol min/L	High intra- and interindividual variability	Level 1
5-Flurouracil	Target AUC at steady-state 18–28 mg h/L	Variable systemic clearance (approx. 5 L/min variable up to 100-fold)	Level 1
Mitotane	Target trough concentrations: 14–20 mg/L	Higher exposure associated with risk of neurological toxicity	Level 2

AUC area under the concentration–time curve

Individuals who metabolize and excrete the active substance slowly have larger systemic exposures and vice versa (e.g. UGT1A1 activity and the risk of irinotecan induced myelosuppression).

TDM is routinely practised for select antibiotics, antifungals, antiepileptics, immunosuppressive agents, neuroleptics and antiretroviral drugs. Important considerations for TDM of a drug include the absence of an easily measurable biomarker for drug effect(s), need for long-term therapy, presence of a validated sensitive bioanalytical method for the drug, significant interindividual and relatively low intra-individual variability, narrow therapeutic index, presence of a defined and consistent exposure–response (efficacy/toxicity) relationship and a feasible dose-adaptation strategy [5].

In oncology, TDM is indicated for methotrexate, busulfan, 5-flurouracil, carboplatin, mitotane and imatinib. Some of the novel-targeted drugs belonging to the family of tyrosine kinase inhibitors and monoclonal antibodies have significant interpatient variability in addition to having exposure–effect relationships for response and/or toxicity. Thus, more candidate drugs are likely to emerge in future for TDM including 13-*cis*-retinoic acid, sunitinib, sorafenib, nilotinib, dasatinib, cetuximab, rituximab and bevacizumab [6]. Table 1 lists drugs for which therapeutic monitoring is indicated in oncology.

5 Risk Versus Benefit

Anticancer drugs have off-target effects on rapidly proliferating cells including the bone marrow, gastrointestinal tract, hair follicle and gonads. Common toxicities encountered therefore include neutropenia, thrombocytopenia, diarrhoea, alopecia and infertility, although other organs may also be affected by specific drugs such as doxorubicin-induced cardiac toxicity and bleomycin-induced pulmonary fibrosis. Consequently, majority of cytotoxic drugs are having narrow therapeutic index. The graphical representation of therapeutic index is shown in Fig. 4.

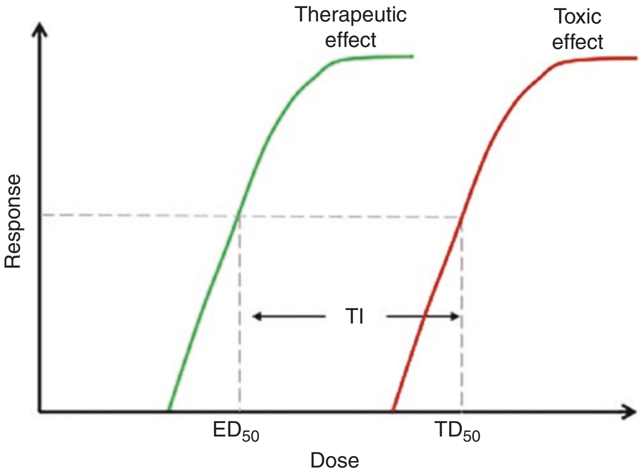

Fig. 4 Therapeutic index: Dose–response curves for efficacy (green curve) and toxicity (red curve) are shown. ED_{50} and TD_{50} are the doses that are effective in and toxic to 50% patients respectively. The ratio between the TD_{50} and ED_{50} is the therapeutic index (TI)

6 Pharmacovigilance

Pharmacovigilance, as defined by WHO, is the science and activities relating to detection, assessment, understanding and prevention of adverse effects or any other drug-related problem [7]. The high incidence of toxicities and narrow therapeutic window of antineoplastic agents necessitates constant monitoring of adverse events long after a drug is approved for human use. Clinical trials are not able to uncover the rare and late toxicities of new drugs, and hence routine surveillance of these adverse events is carried out during the post-marketing period [8]. The risk associate with any treatment has to be weighed against its intended benefits. Hence, while neutropenia may not be an acceptable toxicity of a drug used for the treatment of minor ailments, it is generally accepted for anticancer agents. Pharmacovigilance activities in the past have led to black box warnings (e.g. sunitinib and pazopanib-induced hepatotoxicity, embryo–fetal death caused by vismodegib, ponatinib-induced arterial occlusions) and even recall of drugs (e.g. gemtuzumab indicated for acute myeloid leukaemia was withdrawn in the US due to increase in the risk of death; trovafloxacin, an antibiotic, was withdrawn from EU and US markets due to increase in the risk of liver failure; phenformin an antidiabetic agent was withdrawn due to risk of severe lactic acidosis).

7 Drug Interactions

Changes in the safety and efficacy profile of a medication when co-administered with other drugs or in the presence of environmental pollutants or food is known as drug interaction. Approximately one-fifth of all adverse reactions to drugs are due to drug interactions [9]. Drug interaction mostly deals with drug–drug interactions (DDI), but the pharmacokinetics and/or the pharmacodynamics of drugs can be altered by various other substances such as food [10], nutritional supplements [11], formulation excipients and environmental factors (such as cigarette smoking).

Drug interactions can be the result of altered pharmacokinetics, pharmacodynamics or a combination of mechanisms. The alterations in absorption, distribution, metabolism or elimination of one drug by another drug or substances refers to the pharmacokinetic interactions.

When two or more drugs or substances are co-administered together and have similar molecular targets, the additive effects might result in excessive response or toxicity. Similarly, if the drugs have an opposing effect, it can reduce the response to one drug or both drugs. This is known as pharmacodynamic interactions. Table 2 lists clinically significant drug interactions.

Table 2 Clinically significant drug interactions

Anticancer drug	Concomitant drug	Mechanism	Recommendation
Crizotinib, Dasatinib, Erlotinib, Gefitinib, Lapatinib and Pazopanib	Acid suppressive agents (PPIs, H2As and antacids)	The absorption of these TKIs is significantly affected by concomitant use with acid suppressive agents	The combination of acid suppressive agents and TKIs must be avoided, if possible, if not, both drugs must be taken with a significant amount of time in between to prevent any interaction
Axitinib, Crizotinib, Dasatinib, Erlotinib, Gefitinib, Imatinib, Lapatinib, Nilotinib, Pazopanib, Regorafenib, Ruxolitinib, Sunitinib, Vemurafenib	Strong CYP3A4 inhibitors—ketoconazole, itraconazole and voriconazole Strong CYP3A4 inducers—rifampicin and enzalutamide	PK of TKIs (especially $C_{\max}$ and AUC) can be significantly altered by concomitant use with CYP3A4 inhibitors/inducers	In case the combination is used, dose adjustments are highly recommended
Crizotinib, Gefitinib, Lapatinib, Nilotinib, Pazopanib, Sorafenib, Sunitinib, Vandetanib, Vemurafenib, Tamoxifen	QTc interval-prolonging 5HT3 antagonists, antibiotics, ondansetron/granisetron/sotalol/erythromycin/levofloxacin/methadone/risperidone/azithromycin antifungals, and over-the-counter drugs (e.g., domperidone)	The QTc-interval can be significantly prolonged by concomitant use of these drugs	In case the combination is used, ECG should be taken 24–48 h before and 1 week after initiating the therapy
Pazopanib, Sunitinib, Crizotinib, Lapatinib	P-glycoprotein substrates with a narrow therapeutic window (e.g. digoxin, ciclosporin and tacrolimus), lapatinib	P-glycoprotein inhibition increased digoxin AUC by 80% and decreased pazopanib AUC by 59%	In case the combination is used, it should be liberally monitored for, e.g. by therapeutic drug monitoring
Sunitinib, Nilotinib Pazopanib, Lapatinib	Grapefruit juice	Enzymes in grapefruit inhibit CYP450-3A4 associated metabolism	This combination should be avoided
Methotrexate	Prednisolone, Amoxycillin	Prednisolone and penicillin may reduce methotrexate clearance	Close monitoring of serum methotrexate levels is required

PPI proton pump inhibitors, *H2A* H_2 receptor antagonist, *TKIs* tyrosine kinase inhibitors, C_{max} maximum plasma drug concentration, *AUC* area under the concentration–time curve, *QTc* corrected QT interval, *ECG* electrocardiogram

8 Special Population

Liver and kidney are the major organs responsible for the elimination of drugs from the body. Dysfunction of either of these organs can lead to alteration of drug pharmacokinetics. Renal insufficiency is more common among cancer patients compared to the general population. Up to a quarter of cancer patients will have stage 3 or 4 kidney disease at some point during their treatment (i.e., GFR ≤ 60 mL/min) [12]. Cancers that commonly metastasize to the liver such as breast and colorectal cancers are likely to cause hepatic dysfunction [13].

8.1 Dosing Recommendations in Kidney Disease

Renal dysfunction causes a variety of pharmacokinetic alterations like reduced metabolic capacity of the drug, volume of distribution may be affected due to alterations in tissue binding, reduced renal excretion and production of toxic compounds. These alterations in pharmacokinetics necessitate dosage adjustment in renal impairment. Most of the anticancer agents require renal dosage adjustment. According to the Kidney Disease: Improving Global Outcomes (KDIGO) clinical practice recommendation, dosing in renal impairment should be according to the approved product labelling [14]. Drugs relatively safe in renal impairment are 5-fluorouracil, irinotecan, imatinib, abiraterone, azacitidine, panobinostat, axitinib and idelalisib. Table 3 lists the anticancer drugs for which dosage adjustment is required in renal dysfunction.

8.2 Dosing Recommendations in Hepatic Impairment

In cancer patients, hepatic dysfunction is more common than renal dysfunction. Organ dysfunction can be due to pre-existing diseases such as cirrhosis, metastasis or due to the toxic effects of drugs. Hepatic dysfunction alters drug's pharmacokinetics. The various alterations are rate of drug metabolism, for drugs which are eliminated in the bile or faeces clearance of the drug will be reduced, portal hypertension alters the absorption of the drug and highly albumin bound drugs will have increased free concentrations due to low albumin production by the liver.

Table 3 Drug requiring dose modifications in renal disease

Drugs	Dose adjustment in renal impairment [15–17]
Bendamustine	If CrCl <40 mL/min—do not use
Bleomycin	• CrCl 40–50 mL/min—reduce dose by 30% • CrCl 30–40 mL/min—reduce dose by 40% • CrCl 20–30 mL/min—reduce dose by 45% • CrCl 10–20 mL/min—reduce dose by 55% • CrCl 5–10 mL/min—reduce dose by 60%
Capecitabine	• CrCl 30–50 mL/min—reduce dose by 25%CrCl <30 mL/min—do not use
Carboplatin	Dose based on Calvert's formula • CrCl <30 mL/min—do not use
Cisplatin	• CrCl 46–60 mL/min—reduce dose by 50% • CrCl 31–45 mL/min—reduce dose by 75% • CrCl <30 mL/min—do not use
Cytarabine	• CrCl 40–60 mL/min – If dose >2 g/m^2/dose—reduce to 1 g/m^2/dose – If dose is 0.75–1 g/m^2/dose—reduce to 0.5 g/m^2/day • CrCl <40 mL/min—25% of full dose – If dose >0.75 g/m^2/dose, give ≤200 mg/m^2/day
Daunorubicin	If SrCr >3 mg/dL—reduce daily dose by 50%
Fludarabine	• CrCl 30–70 mL/min—reduce dose by 50% • CrCl <30 mL/min—do not use
Methotrexate	For low doses (<1 g/m^2) • CrCl 30–60 mL/min—50% of full dose • CrCl <30 mL/min—do not use For high doses—consider TDM
Oxaliplatin	• CrCl >30—No dose reduction • CrCl <30 mL/min—Decrease dose to 65 mg/m^2
Pemetrexed	If CrCl <45 mL/min—do not use
Topotecan	• CrCl 30–60 mL/min—reduce dose by 25% • CrCl 10–30 mL/min—reduce dose by 50% • CrCl <10 mL/min—do not use

CrCl creatine clearance, *SrCr* serum creatinine

Table 4 Drugs requiring dose modifications in hepatic disease

Severity of liver dysfunction	Drugs requiring ≥75% dose reduction or omitting of drug	Drugs requiring 50% dose reduction	Safe drugs
Mild (Bilirubin ULN-2 mg/dL)	Docetaxel Irinotecan Paclitaxel	Vincristine Vinblastine	Gemcitabine[a]
Moderate (Bilirubin 2–3 mg/dL)	–	Doxorubicin Etoposide Vinorelbine	–
Severe (Bilirubin >3 mg/dL)	Doxorubicin[b] Etoposide Vincristine, Vinblastine, Vinorelbine, Imatinib	–	Oxaliplatin Topotecan 5-Fluorouracil, Capecitabine Cyclophosphamide[c]

ULN upper limit of normal

[a] Decrease the dose by 20%, increase gradually

[b] Idarubicin does not require dosage adjustment in hepatic dysfunction; epirubicin requires dose adjustment based on AST (aspartate aminotransferase) elevation. Dose reduction is required by 25%, 50% and 75% when the AST levels are 150–250, 250–500, >500 IU/L, respectively

[c] To be administered at 75% of standard dose

There is no standardized system with which to define liver dysfunction in patients with malignancy. Furthermore, various sources often differ in dosing recommendations, which further complicates management of patients with impaired hepatic function. Table 4 enumerates the dosing recommendations for anticancer drugs for varying degrees of hepatic dysfunction.

8.3 Dose Modifications in Obesity

Obesity is an epidemic which is spreading very fast due to changing lifestyles of people around the world. Metabolic dysregulation is often observed in obesity, leading to increase in circulating levels of insulin, IGF-1, adipokines, cytokines and pro-angiogenic factors, which are known to promote cancer development and progression [18, 19]. It is associated with certain physiological alterations that may have a bearing on drug disposition including decreased cardiac function and tissue perfusion, higher volume of distribution of lipophilic drugs and highly variable creatinine clearance which poses a challenge while dosing chemotherapeutic drugs. Obese individuals have higher total lean body mass, and the volume of distribution of hydrophilic drugs is well correlated than that for lipophilic drugs.

Based on the individual drug characteristics, their levels in the plasma may be much different in obese and non-obese patients with similar tissue concentrations [20]. In the past, several alternative descriptors of weight have been used while calculating the dose of chemotherapeutic drugs in obese cancer patients. These include dose capping, dose banding, flat-fixed dosing and using ideal body weight, adjusted body weight, lean body weight instead of total body weight. Alternatively, restricting the dose by capping BSA to 2 m^2, or increasing the duration between treatments are also practiced for the fear of inducing toxicity. However, recent evidence points at higher treatment failure rates or lower overall survival in obese patients when such dosing strategies are adopted.

The following are a few recommendations from ASCO while managing obese cancer patients [21]:

- Actual body weight should be used for dosing chemotherapeutic drugs. It is particularly important when the goal of treatment is curative.
- Comorbidities should be considered for obese individuals, particularly the choice of chemotherapy which need higher doses and association of toxicities with the comorbid conditions.
- The dose de-escalations due to side effects should be done consistently for both obese and non-obese patients.
- For certain chemotherapeutic drugs, the established dosing regimen should be adhered to irrespective of the BMI. For instance, vincristine dose should not exceed 2 mg per dose, and the maximum lifetime dose of bleomycin should not exceed 400 units because of the risk of neurotoxicity and pulmonary fibrosis, respectively, at higher doses, and carboplatin is always dosed based on kidney functions.

9 Clinical Pharmacology in Drug Development

9.1 Biomarkers

According to the National Cancer Institute, a biomarker is 'a biological molecule found in blood, other body fluids, or tissues that is a sign of a normal or abnormal process, or of a condition or disease' [22]. With improved understanding and interpretation of genomic information, next-generation sequencing data will aid in the choice of drug therapy and dosing regimen in the clinical setting. Importance of molecular targets is exemplified by EGFR. Anti-EGFR-targeted antibodies have shown activity in the treatment of non-small cell lung carcinoma (NSCLC) and in a variety of epithelial tumour types, including head and neck cancers and advanced colorectal cancer. This is also true for other targeted drugs such as crizotinib for ALK gene rearrangements. Biomarkers are broadly classified into pharmacodynamic, predictive and prognostic markers.

9.1.1 Pharmacodynamic Biomarker

A pharmacodynamic (PD) biomarker is used to indicate whether the biological effect has occurred on exposure to a drug. PD markers provide information on the direct pharmacological effect of a drug on its target. In the preclinical development phase, the PD biomarkers are used to design drugs which inhibit specific molecular targets. In clinical trials, PD biomarkers help in optimizing the dose of the drug, by correlating the extent of its modulation with the concentration of drug in tumour or surrogate healthy tissues. Thus, the term optimal biological dose was introduced. For example, dose selection of imatinib in early trials was guided by the inhibition of BCR-ABL tyrosine kinase in circulating peripheral blood leukemic cells [23].

9.1.2 Predictive Biomarker

A predictive biomarker is defined as a marker having the potential to discriminate individuals who are more likely than similar individuals without the marker to experience a favourable or unfavourable effect from exposure to a drug [24]. Biomarker-based study designs are generally proposed for targeted drug therapies. The predictive markers are often co-developed with the drug. For instance, in early clinical trials, the relative expression of the marker in tumor with respect to normal tissue is investigated, and any relevant thresholds of marker positivity are selected for application in later trials. In phase II trials, marker-based subpopulation where efficacy of a targeted therapy is most promising is validated. Phase III trials involves randomized treatment

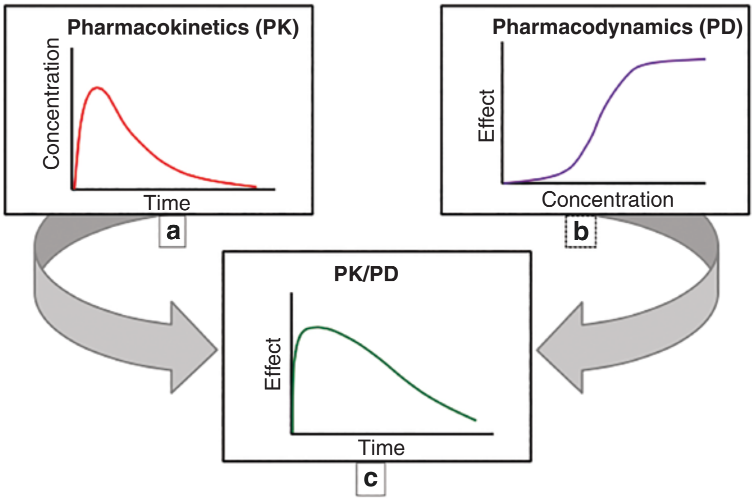

Fig. 5 PK/PD modelling—graphical representation: Pharmacokinetics profiles the change in drug concentration as a function of time (**a**). Pharmacodynamics depicts the change in response as a function of drug concentration (**b**). PK/PD modelling establishes the time course of response with respect to drug administration (**c**). The variability in response and the factors (co-variates) contributing to the variability are quantitatively expressed

comparison in the population believed to benefit from marker directed treatment. For example, BReast CAncer genes 1 and 2 (BRCA1/2) mutations were used as predictive biomarkers in platinum-sensitive ovarian cancer, to identify patients likely to respond to PARP inhibitors [25].

Enrichments Designs

Enrichment is the prospective use of any patient characteristic—demographics, pathophysiologic, historical, genetic and others—to select a population of patients who are more likely to benefit from the drug. Enrichment design is employed primarily in late-phase trials (Phase II or Phase III) and involves enrolling only the biomarker-positive patients and comparing the test drug against the standard treatment only in the biomarker-defined subgroup.

Advantages

- Improved efficiency and feasibility of the trail.
- Enhanced benefit versus risk, especially if the intervention is associated with severe toxicity.
- Efficient in terms of speed and cost.

9.1.3 Prognostic Biomarkers

A prognostic biomarker is a biomarker that is used to predict the likelihood of a clinical event such as recurrence of disease or progression in patients with the disease or medical condition of interest. In clinical trials, prognostic biomarkers define the study population and help in formulating the study objectives. They must be taken into account while analysing the outcomes of a study so as to obtain accurate estimates of the treatment differences and to evaluate results across studies. For example, chromosome 17p deletions and TP53 mutations prognosticate overall survival in chronic lymphocytic leukaemia (CLL) and should be accounted for in the survival analysis of new interventions for CLL in randomized phase 3 clinical trials [26].

9.1.4 PK/PD Modelling (Fig. 5)

The term PK/PD (pharmacokinetic and pharmacodynamic) modelling refers to a data-driven exploratory analysis based on a mathematical/statistical model that quantitatively describes the relationship between drug exposure (PK profile) and response (PD effect). The models are useful to determine how much exposure is needed, and for how long, to exert the desired effect. PK/PD modelling and simulation is a widely used tool in drug development. The models are useful in predicting the pharmacological response at various dosing regimen within a species, and further for upscaling the dose across species.

PK/PD modelling and simulation can make impact at all the stages of drug development. A PD model based on preclinical or biomarker data, or a PK model based on Phase I data are used for designing subsequent phases of clinical trials. In late phase clinical trials, modelling and simulation can be used to assess the impact of covariates such as subgroups, co-morbidities, concomitant medication and pharmacogenetics on the outcome of treatment. Moreover, the data is useful to assess the need for dose adjustment in special populations. In fact, a proactive model-based analysis could alleviate need for additional clinical trials in special populations. For instance, the use of oxcarbazepine monotherapy in children was approved based on PK/PD modelling of data generated in adults.

Population PK/PD analysis modelling (Pop-PK) focuses on merging patient covariates with PK/PD parameters to enable dose individualization. Pop-PK studies identify and quantify sources of variability in the pharmacokinetics of a drug in the patient population. Understanding the patient characteristics that determine the pharmacokinetics can then be used to customize pharmacotherapy. Population modelling typically involves large patient cohorts, but fewer samples (sparse sampling) from each individual and hence it is useful for investigating patient groups or conditions that are not easily studied, such as preterm babies. Not surprisingly, pop-PK is being used more often in drug development. Of note, it is useful when pharmacokinetics of a drug is likely to vary between subgroups of the population.

10 Pharmacoeconomics

Pharmacoeconomics (PE) is a subset of health economics which deals with the measurement and comparison of the costs of drug therapies with one another with a firm focus on healthcare systems and society [27]. A comprehensive PE analysis using economic evaluation methods of healthcare products and services, especially pharmaceuticals, increases their acceptance by healthcare professionals and end users.

10.1 Assessment of Costs and Outcomes

This is the initial step in PE evaluation. Assessing costs and consequences of health care management depends, to a large extent, on the perspective of evaluation. PE evaluation of the value of a product or service can be done from patient, provider, payer and societal perspectives. Patient perspective is particularly important when healthcare is an out-of-pocket expenditure as is the case in most developing countries. Costs can be categorized into various types, as shown in Table 5.

10.1.1 Outcomes

Outcomes of the intervention can be measured in monetary aspects or non-monetary aspects such as QALY (quality adjusted life years) gained. QALY is an indicator of the benefit of health outcomes. For instance, QALY gives as idea about the additional duration of life of a reasonable quality a person might gain out of treatment. It is pertinent to note that outcomes could be either positive or negative. Positive outcomes are a measure of the drug's efficacy, whereas outcomes such as side effects, development of drug resistance and treatment failure are deemed as negative.

10.2 Pharmacoeconomic Evaluation Methods (Fig. 6)

Healthcare provided at a facility should demonstrate a balance of clinical, economic and humanistic outcomes.

Table 5 Categorization of cost

Type of costs	Description	Examples
Direct medical costs	Costs that involve medical products and services used to prevent, detect and/or treat a disease [28]	Drugs, medical supplies and equipment, laboratory and diagnostic tests, hospitalizations and physician visits
Direct non-medical costs	Costs for non-medical services (do not involve purchasing medical services)	Transportation charges to and fro from healthcare facilities and emergency department, child or family care expenses, special nutrition and various other miscellaneous out-of-pocket expenditure
Indirect nonmedical costs	Cost of reduced productivity [27–29]	Loss of Wages due to morbidity and hospitalization
Intangible costs	Non-financial outcomes of disease and medical care [27]	Include pain, suffering, inconvenience and grief and other emotional damage that cannot be measured objectively

PE pharmacoeconomics, *CEA* cost-effective analysis, *CUA* cost utility analysis, *NSCLC* non-small cell lung carcinoma, *QALY* quality-adjusted life years

Fig. 6 Types of pharmacoeconomic analysis

The pharmacoeconomic evaluation techniques can be categorised as economic and humanistic evaluation methods.

10.2.1 Economic Evaluation Methods

Economic evaluation compares alternative courses of action in terms of their costs and consequences [30]. The various types of economic evaluation methods are:

- Cost minimization analysis—the outcome is measured comparing the cost of two or more treatments.
- Cost–benefit analysis—measures both cost and benefit in monetary terms of various interventions.
- Cost-effectiveness analysis—the outcome is measured in natural terms such as life years saved or functional improvements (units of blood sugar or blood pressure).
- Cost-utility analysis—the outcome is based on QALY.

10.2.2 Humanistic Evaluation Methods

Patient preferences, patient satisfaction and health-related quality of life (HRQOL) are becoming increasingly important in pharmacotherapy decisions [31]. These parameters often have physical, emotional and social impact on the patients [30]. HRQOL is usually assessed using patient-completed questionnaires. The questions could be concerned with general well-being or specific for a disease or state of health. Some of the studies that used PE outcome measures are listed in Table 6.

10.3 Pharmacoeconomics in Oncology

Thus, the value of pharmacotherapy could be quantified using the principles of PE by balancing costs and outcomes. It plays a very important role in ensuring the delivery of cost effective and equitable healthcare.

Table 6 Application of cost analysis in oncology

Study description	Cost-effectiveness comparators	Result of PE
CEA for the first-line management of advanced NSCLC of non-squamous cell histology [32]	The various comparator arms used were • Cisplatin and pemetrexed • Cisplatin and gemcitabine • Carboplatin and paclitaxel • Carboplatin, paclitaxel and bevacizumab	Cisplatin and pemetrexed combination was found to be cost effective in this analysis
CEA for the second-line management in NSCLC [33]	Docetaxel was compared with pemetrexed	Docetaxel was found to be most cost effective
CUA of ovarian cancer [34]	Platinum-based chemotherapy versus taxane and other regimens	Platinum-based regimen was found to be better in terms of QALY gained

PE pharmacoeconomics, *CEA* cost-effective analysis, *CUA* cost utility analysis, *NSCLC* non-small cell lung carcinoma, *QALY* quality adjusted life years

11 Personalized Medicine

A drug proven to be efficacious in many patients often fails to work in other patients. The understanding of individual variation in response to a drug helps us to bring the concept of personalized medicine. The latest developments in the field of pharmacogenetics, pharmacogenomics and use of biomarkers help us understand these differences to achieve personalized care. The two approaches to personalized medicine are as follows:

1. Directing targeted agents at unique molecular features of cancer cells
2. Modulating the immune response to tumour through immunotherapy [35]

Table 7 List of drugs exhibiting pharmacogenetic variations

Gene	Encodes	Variants	Affected drugs	Effects
TPMT	TPMT enzyme	*TPMT*3C*, *TPMT*3A*	Thiopurines	TPMT*3A variant is rapidly degraded, leading to prolonged effects of 6-mercaptopurine causing severe myelosuppression Recommendations: Homozygous TPMT—reduce dose by 90%; Heterozygous TPMT—reduce dose based on tolerability
MTHFR (677C>T)	MTHFR enzyme	677 CT 677 TT	Methotrexate	CT has 60% of normal enzyme activity. TT has about 30% of enzyme activity. Carriage of MTHFR 677 T variants has been associated with increased risk for methotrexate toxicities (hematologic, hepatic, and mucosal toxicity)
UGT 1A1	Uridinediphosphate glucuronosyltransferase 1As (UGT 1A1)	UGT 1A1 *28 UGT 1A1 *6	Topotecans—Irinotecan	*28/*28 is associated with higher rates of diarrhoea and febrile neutropenia Recommendations: Homozygous UGT1A1*28—reduce starting dose Used in combination • Weekly dosing—reduce 125 mg/m^2 to 100/75 mg/m^2 • 2-week dosing—reduce 180–120 mg/m^2 Used as monotherapy • Weekly dosing—reduce 125 mg/m^2 to 100/75 mg/m^2 • 3-week dosing—reduce 350–300/250 mg/m^2
CYP2D6	CYP2D6 enzyme	Two or one null allele	Tamoxifen	Reduced activity of CYP2D6 leading to decreased formation of active metabolite—endoxifen leading to inferior outcome in postmenopausal women with early breast cancer
ABCB1	ATP Binding Cassette Subfamily B Member 1	ABCB1 3435 T/T	Taxanes used in breast cancer	Lower toxicity and longer OS
DPD	Dihydropyrimidne dehydrogenase	DPYD*2A DPYD*13	5-Flurouracil	Both variants are associated with higher risk of myelosuppression and neurotoxicity. Recommendations: • Normal DPD activity—No adjustment • Intermediate DPD activity—Reduce dose by 50% • Deficient DPD activity—Use alternative drug

TPMT thiopurine methyltransferase, *6-MP* 6-mercaptopurine, *MTHFR* methylenetetrahydrofolate reductase, *DPD* dihydropyrimidine dehydrogenase

11.1 Pharmacogenetics and Pharmacogenomics

The term pharmacogenetics coined in 1959 defines the science aimed at studying the influence of inherited factors on drug response variability through genetic and pharmacological knowledge. Metabolism of drugs is associated with a variety of genetic polymorphism leading to significant inter-individual variability [36, 37]. Pharmacogenomics is a much broader term that incorporates all genes in the genome that may determine drug response. Table 7 enumerates the effect of pharmacogenetic variations on drug dosing and toxicity.

1 Introduction

Cancer staging is the process of determining the extent of cancer, and it reflects the tumour and host relationship. It is an essential part of cancer management that dictates patient care, predicts prognosis, compares oncological outcomes, and improves cancer control. International Union Against Cancer (UICC) and the American Joint Committee on Cancer Staging and End-Stage Reporting (AJCC) are the two separate bodies working parallelly on the TNM staging, which is the most common staging system used among many.

2 Principles and Need of Cancer Staging

The TNM staging system's ultimate aim is to have its universal applicability regardless of a country's level of resources. It is simple, cheap, objective, and does not require very specialised technology.

The following are the objectives of staging [1]:

1. To assign the proper clinical and pathological staging.
2. Based on anatomical and non-anatomic criteria, staging entails stratification into similar groups, which ultimately aid the clinician in prognosticating the disease and planning treatment.
3. To assist in evaluating and stratifying the results of treatment and management of patients.
4. To ensure uniformity in presenting the treatment results concerning oncological outcomes and facilitate better information exchange between centres for treatment-directed research.

5. To evaluate the results of early detection efforts through population-based screening, surveillance, and through cancer registries.
6. To evaluate treatment guidelines, national cancer control, planning, and research.

2.1 The TNM Oncotaxonomy [2, 3]

The TNM system is an anatomic staging system and specifically applies to solid tumours. It is based on three components: primary tumour (T category), regional lymph nodes (N category), and distant metastasis (M category). The TNM oncotaxonomy provides the necessary structural stencil for the T, N and M and staging system. Haematologic malignancies (leukaemias, lymphomas, and myelomas), by virtue of them not conforming to the pattern of spread characteristic of solid tumours, have separate staging and prognostication systems.

1. *Hollow versus solid organs criteria*:
   There is a fundamental difference between the hollow organs and solid organs, and staging differs depending on the type of affected organ (Table 1).
2. *Specific criteria related to T categories*:
   The extent of the primary tumour is defined by T category. Its description differs depending on the site and the organ of origin. Table 2 shows the specific criteria for T categories.
3. *Specific criteria related to N categories*:
   Rouviere introduced the concept of a first echelon/ station (the first set of lymph nodes receiving the direct drainage of a specific organ) and second echelon/station (the nodes which receive lymph drainage from another lymph node rather than directly; which includes prograde and retrograde drainage) of lymph nodes. He rejected 'the concept of a regional node bearing area.' Table 3 shows the specific criteria for N categories.
4. *Specific criteria related to M categories*:
   The distant metastasis category (M category) specifies whether distant metastasis is present, its location, and burden. Presence of metastasis reflects poor prognosis, and cure is rare. Metastases usually affect the anatomical sites along the venous drainage of the primary organ.
   E.g., Head and neck cancers spread along its venous drainage to the right side of the heart and then to the lung; gastrointestinal cancers drain to the portal vein and then to the liver; prostate cancer spreads via Batson paravertebral venous plexus to the spine.
   M0: No evidence of metastasis
   M1: Solitary metastasis in a single organ without functional impairment
   M2: Multiple metastases to a single organ with minimal functional impairment
   M3: Multiple metastases to multiple organs with minimal to moderate functional impairment
   M4: Multiple metastases to multiple organs with moderate to severe functional impairment

Table 1 Difference between hallow organ and solid organs [2, 3]

Characteristics	Hollow organs	Solid organs
Function	Propel a bolus, vital secretions, undesirable waste products passageway through a system	Glandular function type exocrine glands
Histological architecture	Saccular/tubular organ	Uniform parenchyma with capsule
Anatomic—physiologic units	Multilayered walls and in series	Parallel arrangement and divided into lobes
Capillary network	Avascular mucosa resting on a soft stromal bed rich in lymphatics and capillaries	Intimately related structurally to cellular function
Pair	Concentrically arranged, outer border is a thin layer of mesothelial cells such as the serosa, adventitia, or peritoneum	Paired/bilobed
Surrounding structures	Similar and in-continuity, have sphincters	Separate and different histogenesis
Metastatic spread	Lymphatics and regional nodes	Haematogenous

2.2 Groome's Criteria and the Staging System [4–6]

The T, N, and M system individually creates too many small groups that make a staging system practically tricky. To circumvent this, tumours are grouped into four major stage groups for ease of comparison. However, stage groups are still very heterogeneous. To solve this, the new TNM staging has followed the modified Groome's criteria while incorporating evidence-based non-anatomic factors. The modified Groome's criteria are as follows:

1. Hazard consistency: To gauge the similarity of overall survival (OS) rates for subgroups defined by T, N, and M within each stage group scheme.
2. Hazard discrimination: To assess the differences in OS between stage groups to measure how equally they were spaced. The survival rate associated with a particular group should be significantly different from the one above or below.
3. Explained variance: To estimate the percentage of OS variation defined by the stage grouping. The assigned

Table 2 Special criteria for T category [2, 3, 11]

Specific criteria		T1	T2	T3	T4
Size: The largest dimension size consideration for few organs only (0.5–1.0 cm consist of 10^6 cells and relate to age of the tumour)	Organ				
	Oral cavity, Pancreas, Oropharynx p16 negative	≤2 cm	2–4 cm	>4 cm	More invasive Unresectable in few cancers
	Anal canal, Liver, breast	≤2 cm	2–5 cm	>5 cm	Invades adjacent structures
	Lung	≤3 cm	3–5 cm	5–7 cm	>7 cm, invades adjacent tissues
	Soft tissue tumors—Retroperitoneum	≤5 cm	5–10 cm	10–15 cm	>15 cm
	GIST[a]	≤2 cm	2–5 cm	5–10 cm	>10 cm
	Kidney	≤7 cm	7–10 cm	>10 cm and invasion	Invasion of adjacent structures
Depth of invasion					
(a) Solid organs	Localised		Infiltrate capsule or fibrous layer, ligaments	Infiltrate bone, cartilage, skin	Infiltrate viscera, major nerves, arteries, veins, destruction of bone
(b) Hollow organs	Infiltrates submucosa		Infiltrate muscularis (intrinsic muscles)	Infiltrate extrinsic muscle and serosa	Infiltrate viscera
Mobility	Mobile		Restricted mobility	Fixed	Fixed and destructive
Neighboring structures	Does not infiltrate adjacent or surround structures (superficial)		Extension to Adjacent structures [[b]Attached structures] (deep invasion)	Extension to Surrounding structures ([c]detached structure)	Viscera, causing fistula or sinus (massive destruction)
Surface spread (a) Hollow organ (circumferential involvement)	<1/3 Circumference		1/3 to 1/2 Circumference	1/2 to 2/3 Circumference	>2/3 Circumference
(b) Visceral regions (R)	<½ visceral region (R1)		>1/2 visceral region (R1)	>1 visceral region (R1 + R2)	>2 visceral regions (R1 + R2 + R3)

[a] *GIST* gastrointestinal stromal tumour

[b] Attached structures: Ill-defined boundary between site of origin and these structures. It has similar tissue type and function.

[c] Detached structures: It is separate, but juxtaposed to the site of tumour origin. It has different tissue type and function.

stage should give a good approximation of survival for the individual. It should have high cure/outcome predictive ability.

4. Equitable distribution: The distribution of patients (sample size) is balanced among the groups. To scrutinise the difference in sample sizes across stage groups. Thereby, it maximises statistical power in each group.
5. Likelihood difference: To weigh the difference in the goodness of fit between the models. This is used to assess the various models proposed for staging.

2.2.1 Stage Migration

Hazard discrimination is lost when new prognostic factors or change in technology is applied. This happens due to stage migration. Stage migration leads to a curious statistical phenomenon called ‘the Will Rogers phenomenon’ [7]. This happens due to the shift of the subset of patients with relatively worser outcomes within the previously assigned ‘good’ stage to a higher ‘bad’ stage with poorer outcomes than the previous stage. This improves the survival rate in both groups without any change in individual outcomes. This can be solved with better attention to sound scientific research and clinical taxonomy.

Therefore, it is essential to adopt the staging system, which fulfils all criteria as mentioned earlier.

2.3 General Rules of the TNM System [8, 9]

2.3.1 Staging Groups

Following are the five staging groups:

1. Clinical staging (cTNM): It is used before any treatment. It includes the clinical history, examination, lab tests, biopsy, radiographic, and endoscopic procedures. Surgical exploration without resection is also used to assign the cTNM staging. Whenever there is a doubt regarding the T, N, or M category, the lower category is used. All diagnosis should be confirmed histologically, even for cTNM staging.

Table 3 Special criteria for N category [2, 3]

Specific criteria	N0 Node negative	N1 First station (sentinel)	N2 First station	N3/N3a First station	N4/N3b,3c Second station (juxta regional)
Drainage					
(a) Ipsilateral	–	√Ipsilateral	√Ipsilateral	√Ipsilateral	–
(b) Bilateral/ contralateral	–	√Ipsilateral	√Bilateral or √Contralateral	√Ipsilateral or √Contralateral	√Contralateral
(c) Distant	–	–	–	–	√Distant
Shape	Discoid/ flat	Round	Round	Round, matted	Round
Consistency	Soft to firm	Firm to hard	Firm to hard	Firm to hard	Firm to hard
Size	≤2 cm	2–3 cm	>3 cm and ≤5 cm	>5 cm	>10 cm
Number	–	Solitary	2–3	≥4 and <10	>10 and ≤16
Mobility	Mobile	Mobile (no capsular invasion)	Partial matted (microscopic capsule invasion) muscle (fascia) invasion	Fixed to vessels, bone, large blood vessels, skin (DLI), nerves (PNI)	Fixed and extensive nodal necrosis leading to destruction of bone and skin
Presence of lymph node is assigned as Stage III (or its subdivisions)	Except for few sites, they are down staged and assigned stage I. e.g., DTC <55 years, p16 positive oropharyngeal carcinoma, cervical uterus and stomach cancer. Assigned stage II. e.g., DTC >55 years, nasopharynx, pleural mesothelioma, testis, oesophagus, distal extrahepatic bile duct, exocrine pancreas, lung and breast cancers.				
	Presence of node may be upstaged to Stage IV for mucosal melanoma, liver, thymus, anaplastic thyroid cancer, GIST, renal pelvis, ureter, uveal melanoma, prostate, bone tumours, soft tissue, trunk and of extremities sarcoma.				

DLI dermal lymphatic invasion, *PNI* perineural invasion

2. Pathologic staging (pTNM): It is used if surgery is the first definite therapy. Pathological review of the resected surgical specimen, operative findings, and diagnostic workup from clinical staging are combined for pTNM. It provides essential pathological parameters, which prognosticate and guide subsequent therapy and outcomes.
3. Post therapy or post neoadjuvant therapy (Treatment-related, yTNM): It is used if radiation and/or systemic therapy is given as definitive or neoadjuvant treatment (NADT) before surgery. However, a short course of endocrine therapy in breast cancer or prostate cancer does not meet the criteria for NADT.
    (a) ycTNM: Post NADT (radiation or systemic therapy)—clinical and imaging.
    (b) ypTNM: Post NADT (radiation or systemic therapy and followed by surgery)—pathological.

   The response to NADT is recorded as complete/partial and no response, or by a scoring system or regression score. Presence of non-necrotic viable tumour is required for confirmation of residual tumour. Necrosis, mucin pools, and other reactive and degenerative changes do not confirm the viable tumour and are not considered for residual cancer. Mucin pools and necrotic cells have no role in ypT and ypN.
4. Recurrence or retreatment (rTNM) is used at recurrence after a disease-free interval or progression without a disease-free interval.
    (a) rcTNM: Clinical recurrence staging with/without imaging and biopsy.
    (b) rpTNM: Pathological staging of recurrence. This does not replace clinical (c), previous pathological (p), and/or post-therapy (y) staging.
5. Autopsy (aTNM)—It is used when cancer is discovered incidentally at autopsy. This does not apply to the previously diagnosed cancer patient who has undergone an autopsy.

2.3.2 The TNM Clinical Classification

1. *T category: Primary tumour: Clinical*

cTx: information regarding T category of the primary tumour is not available, or it is not known, or primary tumour cannot be assessed.

cT0: No evidence of a primary tumour.

cTis: Carcinoma in situ.

cT1–4: Increasing size and/or extent of the primary tumour. Based on physical examination, imaging, endoscopy, biopsy, and surgical exploration without resection.

2. *N category: Regional lymph nodes: Clinical*

cNx: No information about the N category or it is unknown or cannot be assessed.

cN0: No regional lymph node involvement.

cN1–3: Increasing involvement of regional lymph nodes.

It may be further divided and subdivided for specific cancers. e.g., Breast, colon, head and neck cancer.

cENE: If a gross extranodal extension is evident on clinical examination.

3. *M category: Distant metastasis: Clinical*

cM0: There are no symptoms/signs of distant metastasis. History and physical examination and/or imaging may be used to assign the cM0 category.

cM1: Clinical/imaging/exploratory surgery or endoscopy are suggestive of distant metastasis without microscopic evidence.

There is no Mx designation. Clinically considered M0 if no proof of metastasis on clinical history or physical findings or imaging. Patient with a negative biopsy of a suspected metastatic site is classified as cM0. Direct extension from the primary tumour or lymph nodes into a contiguous or adjacent organ is not included in the M category.

According to the location (organ) of distant metastasis, M1 category may be specified further with following notations:

M1 PUL: Pulmonary Metastasis
M1 HEP: Hepatic Metastasis
M1 OSS: Osseous Metastasis
M1 SKI: Distant Skin Metastasis
M1 BRA: Brain Metastasis
M1 MAR: Bone Marrow Metastasis
M1 ADR: Adrenal Metastasis
M1 PLE: Pleura Metastasis
M1 PER: Peritoneum Metastasis
M1 LYM: Distant Lymph Nodes Metastasis
M1 OTH: Other

cM0(i+): Circulating tumour cells (CTCs) in blood or Disseminated tumour cells (DTCs) in organs and micrometastasis in the bone marrow are detected by RT-PCR, IHC or cM0(mol+) molecular techniques.

Presence of distant metastasis is assigned as advanced stage IV (A/B/C) except for differentiated thyroid cancer <55 years (Stage II), testis and Gestational trophoblastic neoplasms (Stage III).

2.3.3 The TNM Pathological Classification

1. ***pT: Primary Tumour: Pathological***
   (a) pTx: Histologically, primary tumour cannot be assessed

   pT0: No histological evidence of primary tumour
   pTis: Carcinoma in situ
   pT1–4: Histologically increasing size and/or local extent of primary tumour

   Size is measured in mm and rounded for the nearest whole millimetre

   (b) **Unresectable tumour:**

   pT category is assigned without tumour resection after biopsy confirmation from the primary tumour or microscopic confirmation of the highest pN.

   (c) **Grade**: It is a qualitative assessment of the degree of differentiation, which provides information regarding the risk of metastasis and prognosis. If more than one grade of differentiation is present, then the highest grade is recorded.

   Grade X: Grade of differentiation cannot be assessed
   Grade 1: Well-differentiated
   Grade 2: Moderately differentiated
   Grade 3: Poorly differentiated
   Grade 4: Undifferentiated

   Sometimes Grade 3 may be combined with poorly differentiated and/or undifferentiated, e.g., Esophagus and stomach.

   For thymus and Merkel cell carcinoma, there is no recommended histologic grading system. There are unique grading systems for tumours of specific organs, e.g., breast, prostate, and liver.

   (d) **Lymphovascular invasion (LVI)**:

   LVI Coding:
   0: LVI not present/not identified
   1: LVI present/identified
   2: (L) Lymphatic and small vessel invasion only
   3: (V) Venous (large vessel) invasion only
   4: Both lymphatic and small vessel and venous (large vessel) invasion
   9: Presence of LVI unknown/indeterminate

   Intratumoral or extratumoral; focal or multifocal also noted.

   (e) **Perineural invasion (PNI)**:

   PnX: Perineural invasion cannot be assessed
   Pn0: No perineural invasion
   Pn1: Perineural invasion present

   Intratumoral or extratumoral; focal or multifocal also noted.

2. ***pN: Regional Lymph Nodes: Pathological***
   (a) pNx: Histologically, regional lymph nodes cannot be assessed
   (b) pN0: Histologically, no regional lymph node metastasis

   pN1–3: Histologically, increasing involvement of regional lymph nodes

   The number of lymph nodes removed is documented to provide optimal prognostic information. Even though fewer than the recommended number of nodes are resected, it is categorised as pN0.

   Apart from the number of lymph nodes removed, its location, size of the node, and the node's largest metastatic deposit are also documented.

(c) **Macrometastasis:**

Tumour deposit >2 mm. It is considered pN1.

(d) **Extranodal extension (ENE/ECE/ECS):**

Extension of metastasis through the lymph node capsule into adjacent tissues are documented.

$pENE_n$: None

$pENE_{mi}$: microscopic ENE $\leq$ 2 mm

$pENE_{ma}$: Major ENE >2 mm or gross ENE. Both qualify as pENE (+)

If the tumour directly extends to the lymph node, it is classified as node-positive. Rounded tumour nodules in regional areas are considered nodes that are completely replaced by tumour and are not part of T category.

3. ***pM: Distant Metastasis: Pathological***

pM1: Distant metastasis microscopically confirmed

There is no designation of pM0. Direct extension from the primary tumour or lymph nodes into a contiguous or adjacent organ is not included in the M category.

Metastasis to both sides of a paired organ is considered a single metastatic site.

e.g., Bilateral lung metastasis is considered as one distant site as lung.

If confirmed microscopic evidence of distant metastasis is available, pM1 is used for clinical and pathological stage IV.

e.g., cT3 cN1 pM1, c Stage IV and cT3 cN1 pM1, p Stage IV.

2.3.4 Additional Descriptions

1. **Multiple Tumours**:

Multiple tumours may occur in the same organ at around the same time (synchronous) or at separate points in time (metachronous).

Synchronous primary tumour:

(a) Cancers occurring in the same organ system (or paired organs) with diagnosis date ≤4 months apart. It also includes disease diagnosed at the time of surgery for first cancer, if surgery is the planned first course of therapy.

(b) They have the same histology and occur in one organ. 'm' suffix is used for multiple synchronous 'invasive' primary tumors in a single organ. The tumour with the highest T category is highlighted, e.g. pT3(m) N0M0 or another alternative is to write the number of tumours, e.g. pT2(3) N0M0.

(c) Synchronous primary tumours in paired organs are staged separately, e.g., lung, kidney and breast. However, for thyroid, liver and ovarian tumours, multiplicity is incorporated in T category and, therefore, not staged separately. It does not apply to multiple foci of in situ cancer or mixed invasive and in-situ cancer.

Metachronous primary tumours:

(a) Cancers occurring in the same organ system with diagnosis date are more than 4 months apart. It does not include disease identified during the surgery for the first cancer, if surgery is the planned first course of treatment and is conducted >4 months after the first diagnosis.

(b) Metachronous primary (occurring in the same organ or different organs) are staged independently as new cancer.

2. **Unknown Primary**:

An unknown primary site is assigned T0 if there is evidence of nodal and/or distant spread and a primary source is suspected, but not identified by clinical examination, imaging or histology. T0 is designated when an expected primary site refuses to show any evidence of malignancy. When a primary site cannot be determined by histology, like poorly differentiated carcinoma, it is not categorised as T0, but is just designated as unknown primary.

(a) cT0: If physical examination, imaging, endoscopy and other diagnostic procedures do not identify a primary tumour.

(b) pT0: If after surgical resection of a suspected primary tumour, it does not show the tumour and is not confirmed on biopsy.

(c) T0 Category: In the absence of any evidence or unknown primary, the staging is done according to the clinically suspected anatomic site.

e.g., Metastatic adenocarcinoma in axillary lymph nodes, suspected from breast, T0N1M0, Stage II.

(d) For head and neck sites, T0 category is not used, except for HPV-associated oropharyngeal, EBV-associated nasopharyngeal cancers and major salivary gland cancers.

This is different from T_X. 'T_X' designation is given when the information about a former primary is not available, or the clinical scenario is such that the primary cannot be assessed. 'T_X' category use should be minimised.

3. **Sentinel Lymph Node**:

cN1(sn): If SLN biopsy is done for diagnostic workup, then the positive node is denoted as cN1(sn).

pN1(sn): If SLN biopsy is done as a part of initial surgical management, then the positive node is represented as pN1(sn).

If the patient has undergone a completion lymph node dissection following SLN biopsy, then the suffix is not used. pN1 is used.

pN0 (sn): Negative nodes after sentinel node biopsy.

pN0 (i+) (sn): Isolated tumour cells <0.2 mm in sentinel node biopsy sample.

4. **FNA/Core Biopsy:**

cN1(f): If FNA/Core biopsy is done on lymph nodes as a part of the diagnostic workup, then cN1(f).

pN1(f): If FNA/Core biopsy is done as a part of primary site surgical resection with no lymph node dissection performed, then the positive node is denoted as pN1(f).

If a completion lymph node dissection is done as part of the initial surgery, it is pN1.

5. **Isolated Tumour Cells (ITCs) (i+)**:

   Single tumour cell or small clusters of cells ≤0.2 mm.

   A cluster of <200 cells in a single histological cross-section.

   They do not show proliferation, stromal reaction, or penetration of vascular or lymphatic sinus walls. As they represent in-transit disease and not something that stations and proliferates, their presence in nodes is not usually considered positive except for few aggressive tumours. Therefore, they are categorised as N0 in lymph nodes and M0 in distant sites.

   e.g., Breast and gynecologic cancers; cN0(i+) if detected on diagnostic workup or pN0 (i+) on IHC as a part of surgical management.

   pN0 (mol+) if no tumour cells histologically, however positive by molecular (RT-PCR) findings/ flow cytometry.

   However, in melanoma and Merkel cell carcinoma, they are considered positive. pN1(i+).
6. **Micrometastasis:**

   Tumor deposit >0.2 mm to ≤2.0 mm. cN1 (mi) if detected on diagnostic workup or pN1 (mi) for single node and pN2b (mi) or pN2c (mi) for multiple nodes as a part of surgical management.
7. **Residual Tumour and Surgical Margins:**

   'R' represents the absence or presence of residual cancer after treatment.

   However, the R designation is not incorporated into TNM staging itself, recorded in medical record and cancer registry as essential information for subsequent treatment and prognostication.

   The R categories for the primary site following surgical manoeuvres:

   Rx: Presence of residual tumour cannot be assessed
   R0: No residual tumour
   R1: Microscopic residual tumour
   R2: Macroscopic residual tumour at the primary cancer site/regional nodal sites (does not apply to metastatic disease, which is not resected at surgical exploration)

   After tumour resection, margin status is noted either as negative, microscopic positive, macroscopic positive, or could not be assessed. Presence of disease at the margin of resection indicates the risk of recurrent cancer and more advanced T or N tumour.
8. **Paediatric Tumors:**

   There is no classification of paediatric tumours incorporated in the TNM system. This is because of the lack of an international standard staging system for many paediatric tumours. A recommendation was published in 2014 on paediatric staging to facilitate the collection of the stage by population-based cancer registries.

2.3.5 Stage Grouping [8–10]

Each patient can be placed in 125 different categories, which may be inconvenient for the clinician. Cancer progresses in an orderly, predictable fashion in most cases, though seldom not. The Venn diagram of cancer spread is used to illustrate disease progression and patients with similar prognosis are grouped by using prognostic stage group tables. Thus, the stages are divided into four and denoted by Roman numerals (I–IV).

The unified stage grouping helps to compare patterns of spread rationally. In case of doubt regarding the stage grouping, the lower group is assigned.

Staging Rules

Figures 1, 2, 3, 4, and 5 shows the five rules of staging adopted for the TNM staging.

1. Stage 0:

Stage 0 includes in-situ and non-invasive cancers.

Term 'non-invasive' usually denotes that the disease has not crossed the basement membrane. 'In-situ' means it has not crossed the boundary to attain spreading potential. That boundary could be basement membrane in some cancers like oral cavity or muscularis mucosae in the colon. Generally, it is considered to have no potential for regional or distant spread. So, lymph node assessment is not necessary to assign final pathologic stage 0 for in-situ neoplasia.

   (a) cTis N0 M0, (clinical stage 0is): In situ neoplasia identified during diagnostic workup.

   (b) The category non-invasive (Ta) is only defined in a few cancers (e.g., urinary bladder).

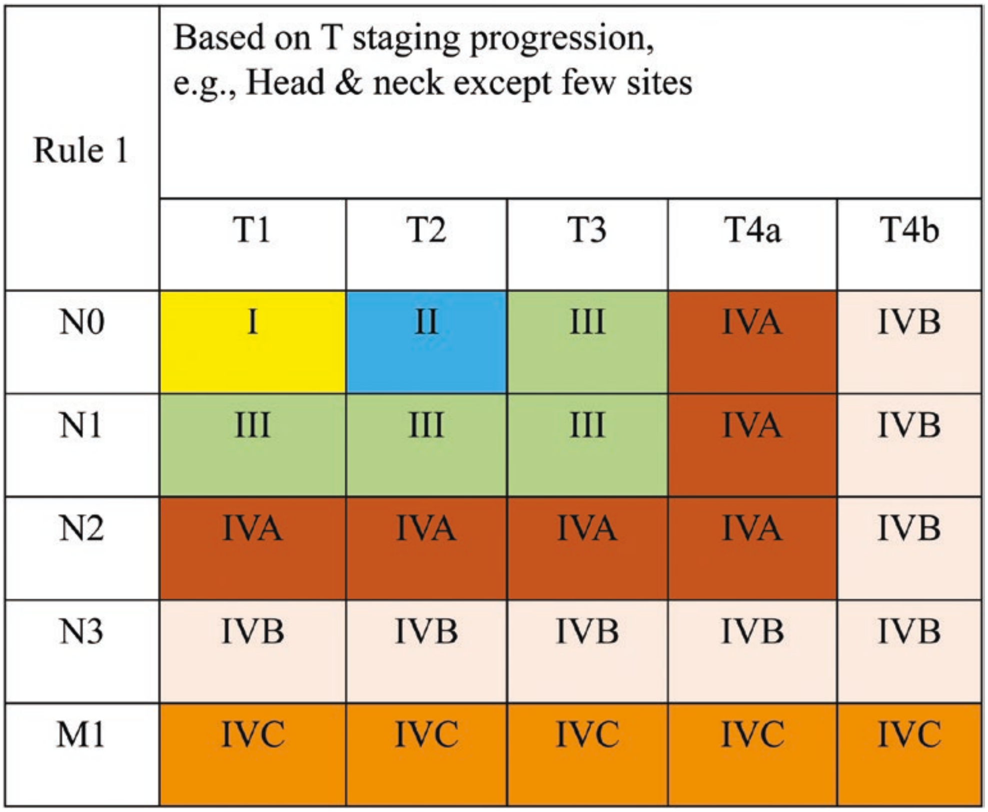
   cTaN0M0, (clinical stage 0a): Non-invasive papillary carcinoma identified during diagnostic workup.

   (c) Rarely pathology may not be able to identify the invasive component and is reported as Tis with regional nodal involvement. In that case, the appropriate stage group may be assigned as per the N category by the physician. However, in the cancer registry, the stage group is not assigned.

   e.g., In breast, ductal carcinoma in situ with nodal metastasis may represent nodal metastasis from an unidentified invasive occult primary cancer.

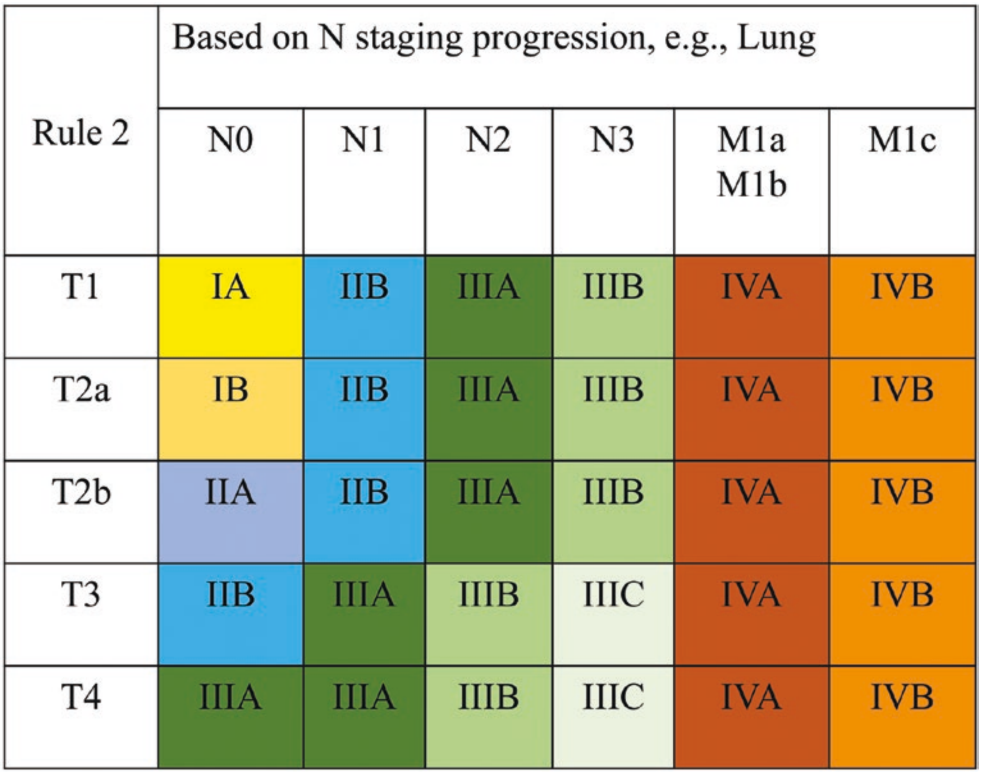
   In melanoma, melanoma in situ with nodal metastasis: It may represent the biologically regressed primary tumour.

2. If a complete pathological response has occurred, then ypTNM is ypT0N0M0; no stage group is assigned and not classified as Stage 0 because that would denote in situ neoplasia.



Rule 1	Based on T staging progression, e.g., Head & neck except few sites				
	T1	T2	T3	T4a	T4b
N0	I	II	III	IVA	IVB
N1	III	III	III	IVA	IVB
N2	IVA	IVA	IVA	IVA	IVB
N3	IVB	IVB	IVB	IVB	IVB
M1	IVC	IVC	IVC	IVC	IVC

Fig. 1 Rule 1 of the TNM staging [9–11]



Rule 2	Based on N staging progression, e.g., Lung					
	N0	N1	N2	N3	M1a M1b	M1c
T1	IA	IIB	IIIA	IIIB	IVA	IVB
T2a	IB	IIB	IIIA	IIIB	IVA	IVB
T2b	IIA	IIB	IIIA	IIIB	IVA	IVB
T3	IIB	IIIA	IIIB	IIIC	IVA	IVB
T4	IIIA	IIIA	IIIB	IIIC	IVA	IVB

Fig. 2 Rule 2 of the TNM staging

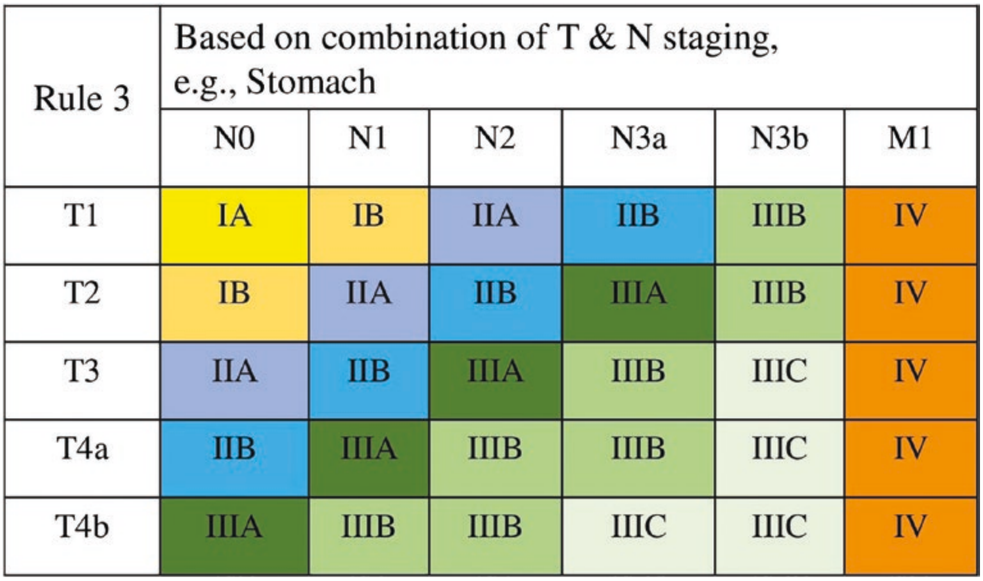


Fig. 3 Rule 3 of the TNM staging

Rule 3	Based on combination of T & N staging, e.g., Stomach					
	N0	N1	N2	N3a	N3b	M1
T1	IA	IB	IIA	IIB	IIIB	IV
T2	IB	IIA	IIB	IIIA	IIIB	IV
T3	IIA	IIB	IIIA	IIIB	IIIC	IV
T4a	IIB	IIIA	IIIB	IIIB	IIIC	IV
T4b	IIIA	IIIB	IIIB	IIIC	IIIC	IV

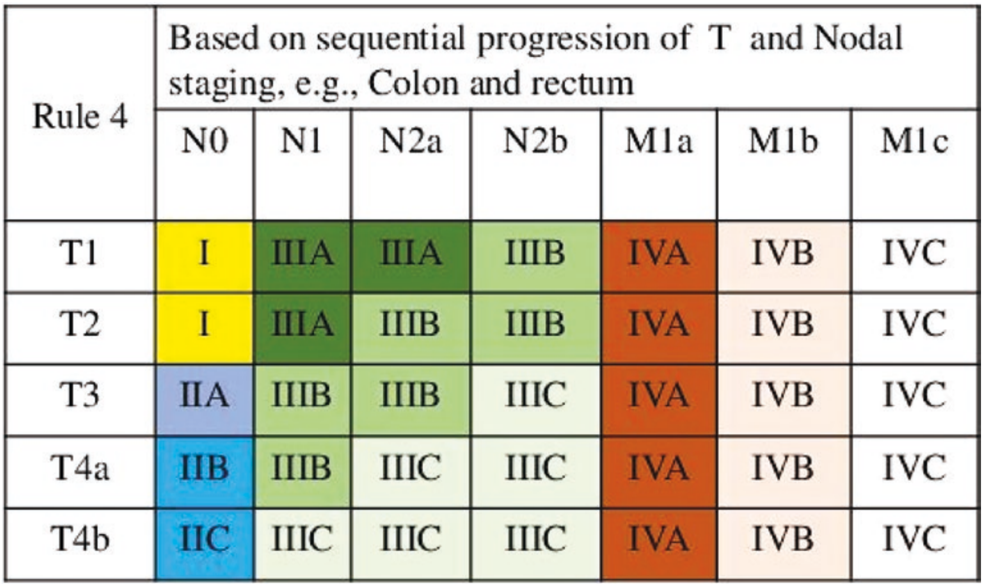

Fig. 4 Rule 4 of the TNM staging

Rule 4	Based on sequential progression of T and Nodal staging, e.g., Colon and rectum						
	N0	N1	N2a	N2b	M1a	M1b	M1c
T1	I	IIIA	IIIA	IIIB	IVA	IVB	IVC
T2	I	IIIA	IIIB	IIIB	IVA	IVB	IVC
T3	IIA	IIIB	IIIB	IIIC	IVA	IVB	IVC
T4a	IIB	IIIB	IIIC	IIIC	IVA	IVB	IVC
T4b	IIC	IIIC	IIIC	IIIC	IVA	IVB	IVC

3. Stage IV: Stage assigned is stage IV if evidence of distant metastasis, even if T or N category is unknown.

2.4 Cancer Staging Systems in Clinical Practice [8, 9, 11]

2.4.1 Supplementary/Alternate Staging/Grading System to TNM System: Few Examples

1. Breast cancer: Scarff-Bloom-Richardson (SBR) (Nottingham) grading system.
2. Prostate Cancer: The Gleason scoring system and the grade grouping (1–5).
3. Hepatocellular cancer: Barcelona clinic liver cancer (BCLC) staging, Hongkong liver cancer (HKLC) staging.
4. Perihilar bile duct: Bismuth-Corlette classification.
5. Gynaecologic cancers: Fédération Internationale de Gynécologie et d'Obstétrique (FIGO) staging.
6. Thyroid cancers: The MACIS prognostic scoring systems, American Thyroid Association (ATA) risk stratification system.
7. Soft tissue sarcoma: The French Federation of Cancer Centers Sarcoma Group (FNCLCC) histologic grading system.
8. Colorectal cancer: Dukes staging system (A–C), Modified Astler-Coller classification (MAC) (A–D).

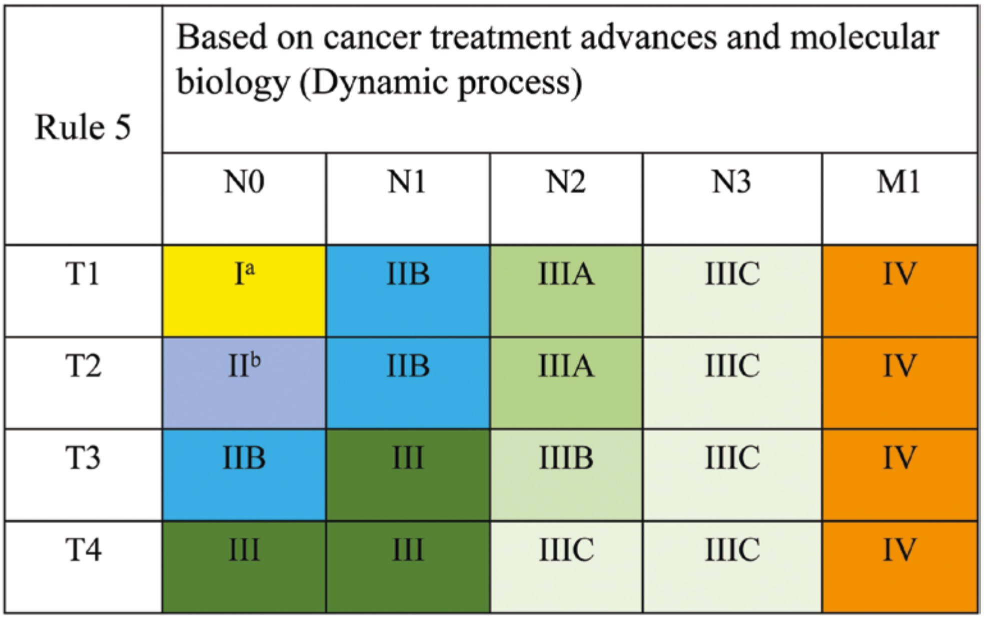

Fig. 5 Rule 5 of the TNM staging

Rule 5	Based on cancer treatment advances and molecular biology (Dynamic process)				
	N0	N1	N2	N3	M1
T1	I[a]	IIB	IIIA	IIIC	IV
T2	II[b]	IIB	IIIA	IIIC	IV
T3	IIB	III	IIIB	IIIC	IV
T4	III	III	IIIC	IIIC	IV

2.4.2 Publications and Organisations Associated with TNM System [1, 8]

Publications

1. World Health Organization (WHO) Classification of Tumours, pathology and genetics, 2000–2016.
2. WHO International Classification of Diseases for Oncology (ICD-O), 2000.
3. American College of Radiology (ACR) Appropriateness Criteria.
4. CAP Cancer protocols.
5. National Comprehensive Cancer Network Clinical Practice (NCCN) Guidelines in Oncology.
6. American Society of Clinical Oncology (ASCO) Guidelines.

Organisations

1. Centers for Disease Control and Prevention, USA (CDC).
2. International Federation of Gynaecology and Obstetrics (FIGO).
3. International Association of Cancer Registries (IACR).
4. International Agency for Research on Cancer (IARC).
5. International Association for the Study of Lung Cancer (IASLC).
6. International Collaboration on Cancer Reporting (ICCR).

2.4.3 The AJCC-UICC Lexicon Project [8]

In January 2012, the UICC and AJCC initiated a comprehensive analysis of staging nomenclature, viz. the AJCC-UICC Lexicon Project.

The staging terminologies should be categorised into four main groups:

1. Anatomic stage: Disease extent and timing/classification, also tumour markers reflect tumour burden. (e.g. serum PSA in prostate cancer).
2. Tumour profile: Morphology, pathological grade, growth pattern, tumour markers, the steroid receptive status (estrogen receptor/progesterone receptor), DNA content (ploidy and S-phase), proliferative indices, viral load molecular and genetic markers. These are predictive, prognostic, and companion diagnostic markers.
3. Patient profile: Age, race, gender, level of education, socioeconomic status, performance status, comorbidity—coronary artery disease, obesity, hypertension, diabetes mellitus, immunodeficiency.
4. Environment: Treatment-related, its availability, education (expertise, access, ageism, healthcare delivery), socioeconomic status, quality of imaging, and quality of management.

2.5 Evolution of Staging System and Their Implications

1. **History of Staging System** [1, 8, 9]

   Cancer of the cervix was first staged in the 1920s. In 1929, the League of Nations Health Organization led the work on 'clinical classification of cancer.' The French surgeon, Pierre Denoix, proposed the 'Tumour—node—metastasis (TNM) system' between 1943 and 1952 based on cancer's anatomic extent. In 1950, the UICC appointed a committee on Tumour Nomenclature and statistics. It launched ‘Uniform technique for a Clinical Classification by the TNM classification’ along with the International Commission on Results of the treatment of cancer (ICPR) in 1953. The Research Commission of the UICC had configured a special committee on clinical stage classification and applied statistics in 1954. The clinical staging for breast and larynx was published in 1958 and revised proposals for breast cancer in 1959. The American Joint Committee for Cancer Staging and End Results Reporting (AJCC) was founded on January 9, 1959. Cancer of head and neck, alimentary tract, breast, urological sites, and skin were staged between 1960 and 1967 (Nine brochures for 23 body site classification proposals). UICC published ‘livre de Poche’ (the first collective TNM handbook) in 1968. In 1980, AJC was renamed to the American Joint Committee on Cancer (AJCC). The UICC and AJCC and collaborated in 1978 and resulted in the simultaneous publication of the staging manual. In 1987, the UICC and the AJCC TNM classification was unified.

2. **Evolution and Its Implication**

   Evolving for over 50 years, the current 8th edition includes 15 organ systems and 130 primary sites (Table 4) [9, 11]. It reflects all the assimilated evidence-based knowledge regarding cancer biology, etiology, prognostic factors, statistical methodology, and recent advances in the field.

Table 4 Evolution of TNM system [1, 8, 10]

Edition UICC 1950	Edition AJCC 1959	TNM Organ system	TNM Primary sites/ disease
1st (1969) Expansion	–	7	27
2nd (1974)	–	8	30
3rd (1978) Checklist	1st (1977)	9	33
3rd (1982) Illustration—Atlas	2nd (1983)	10	36
4th (1987) Unification	3rd (1988)	12	45
4th (1993) Refinement—Supplement	4th (1992)	12	56
5th (1997) Prognostic factors—Monograph	5th (1997) (Adopted staging from other oncology cooperative investigative groups)	11	55
6th (2002) TNM Mobile Edition 2001/02; TNM Online 2003	6th (2002)	11	56
7th (2009)	7th (2009)	11	71
8th (2016)	8th (2016)	15	130

2.5.1 Concerns Associated with the Revisions in Staging System

(a) Newer changes incorporated in the staging system may disturb the staging consistency concerning previously acquired data. Therefore, the anatomical basis is maintained. It maintains consistency with the past versions of staging.

(b) A revised staging system may diminish the comparability of the data over time. Therefore, in general, the TNM revision happens every 5–7 years. This gives sufficient time for implementing the staging system in clinical practice and allows comparisons across historical and contemporary eras.

(c) Too many changes make the staging system more complex to use and practice. Therefore, only clinically essential and relevant changes are incorporated to have broader applicability. They are selected based on available methods of assessment and depending on the need for patient management.

(d) Newer prognostic factors may not apply to low resource countries. Therefore, the anatomic extent as a backbone of the staging system is maintained. It is still applicable to the patient population for whom new prognostic factors are not available due to cost, lack of expertise, logistic issues, or reporting systems.

(e) Tumours with higher histological grade are more aggressive clinically than those with low-grade. However, the cancer staging system seldom relies on the grading system, it is based on the extent of primary tumour and spread to regional lymph nodes or distant metastasis. Incorporation of the tumour grading into the staging system can show a strong survival association, e.g., colorectal cancer.

(f) The TNM staging system is useful as a classification system at a population level. Its utility for the individual patient has been questioned. The 8th TNM cancer staging manual has attempted to address this issue by incorporating molecular markers to supplement the traditional approach.

2.5.2 Types of Changes in the TNM System [10]

(a) Minor 1+: Same TN designation but definition change, e.g. head and neck, penis

(b) Moderate 2+: Designation change T or N, but not stage, e.g. thyroid, breast

(c) Major 3+: Major change T or N, with new criteria and new substage, e.g., nasopharynx, adenocarcinoma thorax

(d) Marked 4+: New T and N criteria definition and shift in stage, e.g. thoracic oesophagus, prostate

(e) New 5+: New TNM staging system, e.g. mucosal melanoma, small intestine adenocarcinoma, adrenal gland

2.6 Prognostic Factors and 'Grid' [9, 12, 13]

Prognostic factors (PF) may explain the heterogeneity associated with a disease's expected course and outcome.

Levels of prognostic factors:

(a) Level I PF: It is statistically significant
(b) Level II PF: It is an independent PF
(c) Level III PF: It is of clinical relevance

2.6.1 Grids of Prognostic Factors

UICC Manual of clinical oncology, 9th edition has proposed the framework for classification of prognostic factors with 'the Grids of prognostic factors' for various cancer sites. It includes a 'subject-based' classification (tumour related, host-related, and environmental-related) and 'clinical relevance-based' classification (essential, additional and new and promising prognostic factors). The grids are reproduced in the 8th edition of UICC TNM classification. Table 5 shows the grid classification and a few examples.

2.7 Changes Observed in the TNM System

2.7.1 C-Factor [8, 9]

The Certainty Factor (C factor) denotes the classification's validity as per the diagnostic method used. The C Factor has been removed in the eighth edition of the Staging system.

Table 6 shows cancer site specific revisions in TNM staging.

2.8 Future of Cancer Staging [3, 14]

The TNM staging is mainly a surgical system built on anatomic parameters. It's a temporal determinism that is based on the contiguous spread of disease. Nomograms and artificial neural networks should be utilised in the future to integrate various relevant prognostic factors. The following elements may be incorporated into the TNM system:

1. Tumour-related: histologic features (especially grade and cell type), location, gross appearance, multiplicity, dimension of margin, ease of resectability, tumour marker levels, hormone receptors positivity, somatic mutations and molecular signature of tumour cells.

Table 5 UICC prognostic factors 'grid' with few examples [9, 12]

		Subject-based classification		
Prognostic factor		***Tumor related*** Anatomic extent Pathological parameters Tumor biology and markers Symptoms related	***Host related*** Host demographics Acquired host factors	***Environmental related*** Interrelationship of Treatment, Quality and Education with Physician, Health care system and Society
Essential **Fundamentally required for decision making**	**Clinical Relevance-Based Classification**	Gleason sum score (Prostate) T, N and M category (Anal canal) Circumferential margins (Rectum) Extracapsular extension (Oral cavity)	Age >70 (Larynx) Menopausal status (Breast) Performance status (Cervix) Germline mutation RBI allele (Retinoblastoma)	Residual disease after resection (Bone) Cigarette smoking (Anal canal) Screening programme (Colon and rectum) Quality of and availability of anticancer therapies (Cervix)
Additional **Not absolutely required for decision making** Finer prognostication No impact on the treatment Stratification of patient		Tumor volume (Larynx) Hypoxia (Oral cavity) CA 19.9 level (Pancreas) CA 125 (Ovary)	Comorbidity (Oropharynx) BRCA 1 or 2 (Breast) LDH (Nasopharynx) Hepatitis activity (Liver)	Nutritional support (Oesophagus) Extent of resection (Stomach) Management by a multidisciplinary sarcoma team (Bone) Centre volume and experience (Colon and rectum)
New and promising **Not enough evidence for use** New factors Prognostication Based on cancer biology		EGFR receptor (Oropharynx) Ki67 (Breast) Molecular profile (Thyroid) FGFR2 mutations (Biliary tract and gall bladder)	Serum MyoDI (Cervix) IL10 and VEGF (Liver) HSV virus (Anal canal) Race: Asian or non-Asian (stomach)	In utero detection of Rb (Retinoblastoma) Immunotherapy (Melanoma) Pathological response to neoadjuvant therapy (Pancreas) Neutron vs. photon radiotherapy (Major salivary glands)

Table 6 Cancer site-specific revisions in TNM staging [9, 11]

Sites	Major changes/revision done in TNM staging
New chapter and/or new TNM staging added	**7th Ed.** Mucosal melanoma of the head and neck, gastrointestinal stromal tumours (GIST), neuroendocrine tumours, Merkel cell carcinoma, appendix, adrenal gland, ocular adnexal lymphoma **8th Ed**. HPV-mediated (p16+) oropharyngeal cancer, cutaneous squamous cell carcinoma of the head and neck, cervical lymph nodes and unknown primary tumours of the head and neck, thymus, parathyroid Soft tissue sarcoma: New staging: head and neck, retroperitoneal, trunk and extremities, thoracic and abdominal viscera, unusual histologies and sites New TNM staging: Pelvis and spine bone sarcomas
Separate/major revisions	**7th Ed.** Intrahepatic bile ducts, perihilar bile ducts, distal bile duct **8th Ed.** Oropharynx (p16-) and hypopharynx, nasopharynx, medullary thyroid cancer, exocrine pancreas, adrenal cortical carcinoma, adrenal neuroendocrine tumours, corpus uteri carcinosarcoma; Soft tissue sarcoma of trunk and extremities, uterine sarcoma, neuroendocrine tumours of: stomach; duodenum and ampulla of Vater; jejunum and ileum; appendix; colon and rectum; pancreas; Combined chapters: ovary, fallopian tube and primary peritoneal carcinoma
No stage grouping yet assigned	Parathyroid, lacrimal gland carcinoma, conjunctival melanoma, brain and spinal cord; soft tissue sarcoma of: orbital; head and neck; abdomen and thoracic visceral and unusual site sarcoma, spine and pelvis bone sarcoma
Detailed concepts/new structure added	Sentinel node, micrometastasis, isolated tumour cells, circulating and disseminated tumour cells minimum number of lymph node harvest, essential TNM, prognostic grid, paediatric malignancies

2. Host-related: comorbidity, immunocompetence, age, gender, race, family medical background (genealogy), nutritional status, and obesity.
3. Therapy-related: Treatment is effective only if patients can tolerate the drug. To address this, the system should include factors that can predict the degree of toxicity to a particular therapy.
4. Environment-related: Access to advanced treatment can change the outcome even among similar stages of the disease.
5. Tumour-Host relationship:
   (a) Symptoms related to cancer
   e.g., Illness index: Even for the same stage of a particular disease, the symptom presentation may vary significantly. The symptoms and metabolic disturbances can very well change the treatment or at least the sequence of treatment.
   (b) Performance status
   The single-most important factor which can influence the treatment plan offered by the clinician.
   (c) Psychological status:
   e.g., Psychologic Index: Based on the effect of the disease on the psychological health.
   (Anxiety, depression, denial, suicidal and psychotic behaviour).
6. Biomarkers: Incorporation of non-linear or interactional molecular (genomic/proteomic) biomarkers into the TNM system can guide molecular biology driven treatment—an improvement over the existing TNM system based therapeutic guidelines with greater accountability for molecular tumour-host interaction.
   This inclusion may evolve a population-based 'one size fits all' model into a personalised approach based on biological determinism while retaining conventional staging's essential attributes.

PBCR	Population-based cancer registries

1 Establishing Cancer Registries

Cancer is contributing significantly to the burden of disease in India. The cancer burden in the country will continue to increase with aging population and changes in life style. In order to understand cancer burden and time trends over the years, there is a need for unbiased data that can provide such information and help in planning and evaluating cancer control measures.

In low- and middle-income countries, including India, the tools to assess disease burden via mortality statistics or routine surveillance mechanism are not available. The cancer registries are therefore very important instruments to measure cancer burden in a defined population.

Cancer registries can be classified broadly into two types: hospital-based and population-based. Hospital-based cancer registries (HBCR) collect the data on cases diagnosed/treated in a defined institution or institutions. These data are extremely useful for developing clinical care in these institutions and also in evaluating survival based on details of treatment. However, these data are not useful to assess cancer burden in the population because they are more or less biased depending upon availability of clinical services and clinicians in the hospital, and they do not capture data of all cancer cases in a given population. Thus, the burden of cancer cases in the population if estimated from hospital data will not only underestimate the burden but may not also indicate leading sites of cancer in the population as hospital data will suffer from referral bias.

Population-based cancer registries (PBCR) collect data of all cancer cases in a defined population; thus, they are able to provide burden of cancer cases in a defined population, and as cancer registration is a permanent process, they also provide information on time trends of cancer over the years. It is not possible to collect information on cancer cases by visiting each and every household or by visiting all physicians or all clinics, particularly in the urban cities. Therefore, registries prepare a list of sources of registration which can give information on cancer cases in that population. There are three major sources of registration; hospitals, laboratories (pathology and radiology) where cancer cases are diagnosed or treated, and death certificates. The sources of registration may also include hospitals that are far away from the location of registry, if the cases from registry area are going to hospitals that are far away for diagnosis/treatment. The assumption for listing these three types of sources of registration for capturing all cancer cases is that at some point cancer cases will visit these sources, which are largely cancer diagnostic centers and/or with facilities for cancer treatment. Because the cancer case may visit more than one cancer care facility, registries develop mechanisms to check the duplicates so as to count cancer cases only once, even if cancer cases get registered at many sources. When registries are established in rural areas, these assumptions are not met. The diagnostic laboratories and hospitals are not available nearby; therefore, cancer patients visit family physicians/primary health care centers or take treatment other than allopathic with available health care providers. For rural registries, therefore, primary health centers, ASHA workers, visit randomly selected households, and household survey once in 5 years is mandatory to ensure completeness of registration. Because of the unavailability of a diagnostic facility, large proportion of cases enrolled by rural registry are based on clinical confirmation.

Unlike western countries, where most of the data collection by registries is passive, i.e., registry receive the data

from various sources electronically, in India data collection is active and partially passive. For active data collection, trained registry staff visit various sources of registration and collect information on a minimum set of variables required by registries. The requirement to set up rural and urban registries and their workflow is summarized in Table 1 and Fig. 1a, b.

The minimum variables that need to be collected by registries are implied in the purpose and definition of registry. The cancer registry's main purpose is to collect all **new cancer** cases in a defined **population, in a defined time period by age and gender**. Thus, minimum variables required for cancer registries are demographic (name, age, and gender) and residential status so as to count the person only once and to ensure that the patient is coming from the same defined population for which cancer burden is being collected. In order to make sure that we are registering only cancer cases, variables related to method of diagnosis and its details are essential. The variable on date of diagnosis is mandatory to ensure the time period when the cancer case was diagnosed. In addition, registries collect information on clinical extent of disease, and minimum treatment details are collected by most of the registries. PBCR usually do not have information on staging or treatment details because it is difficult to collect this information from various sources, which gives rise to cancer cases.

The PBCR mainly produce the following statistics:

1. **Number of cancer cases in given population**: This measure is useful to know the burden of cancer cases and thus helps in planning resources for cancer control.
2. **Crude incidence rates of cancer**: This measure takes into account population. Thus, it is a useful indicator to know how many cancer cases there are per million of population.
3. **Age-standardized rates**: This measure takes into account differences in age distribution of population. Because cancer is a disease of old age, it is important to take into account the differences in age structure of population to study the differences in the rates. This measure is mainly used to compare the rates between two populations.
4. **Truncated age-standardized rates**: This measure is equivalent to age-standardized rates but in age group generally truncated between 35 and 64 years. This is useful to compare the rates in middle ages and also to account for under-registration in cancer cases in older ages.

India does not have a national cancer registry. Many states and rural areas are underrepresented in the registry network

Table 1 Requirement for establishment of rural and urban cancer registries

Rural	Urban
• Formation of Steering committee, Identification of coordinating centre and Principle Investigator	• Formation of Steering committee, Identification of coordinating centre and Principle Investigator

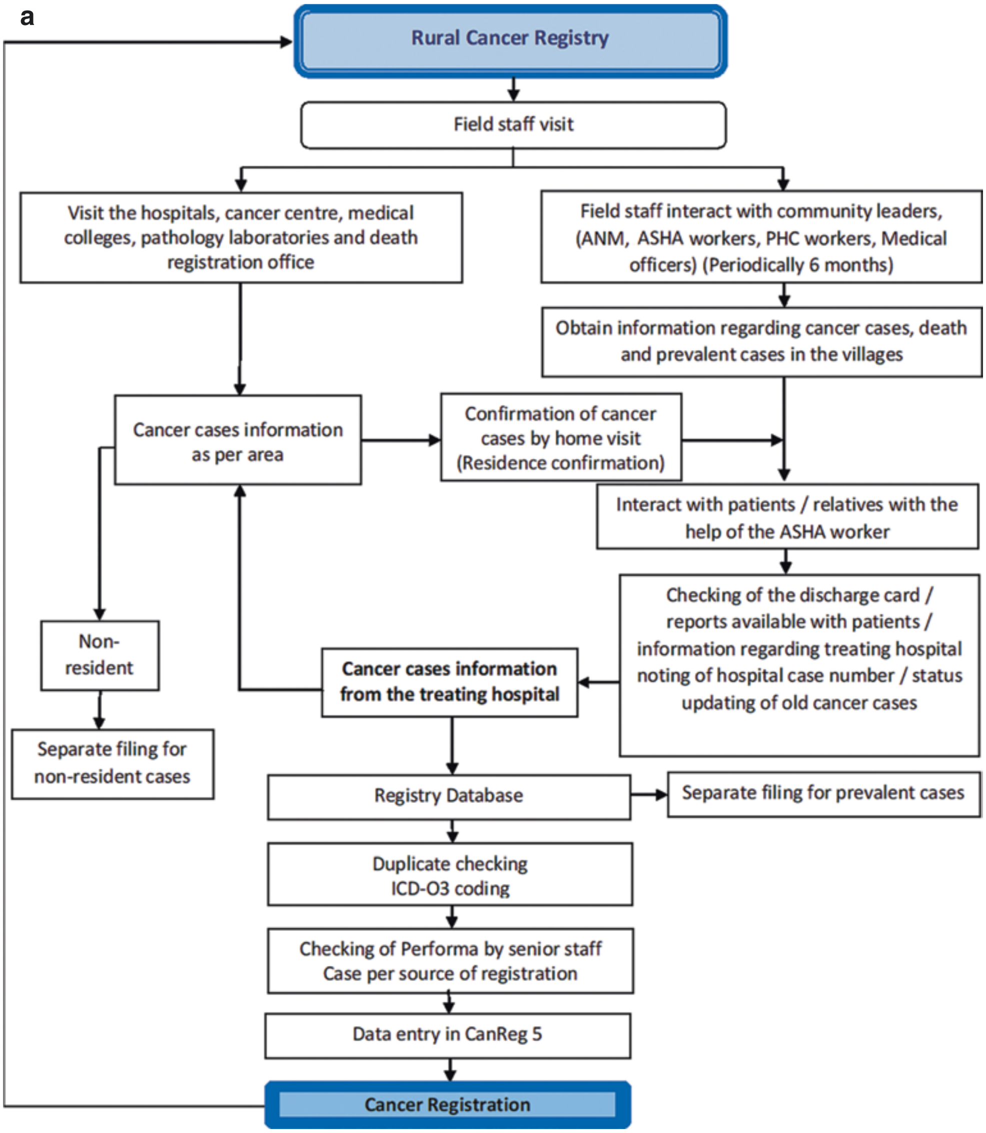
• For 10 lakh population Rs. 25 lakhs	• For 10 lakh population Rs. 20 lakhs

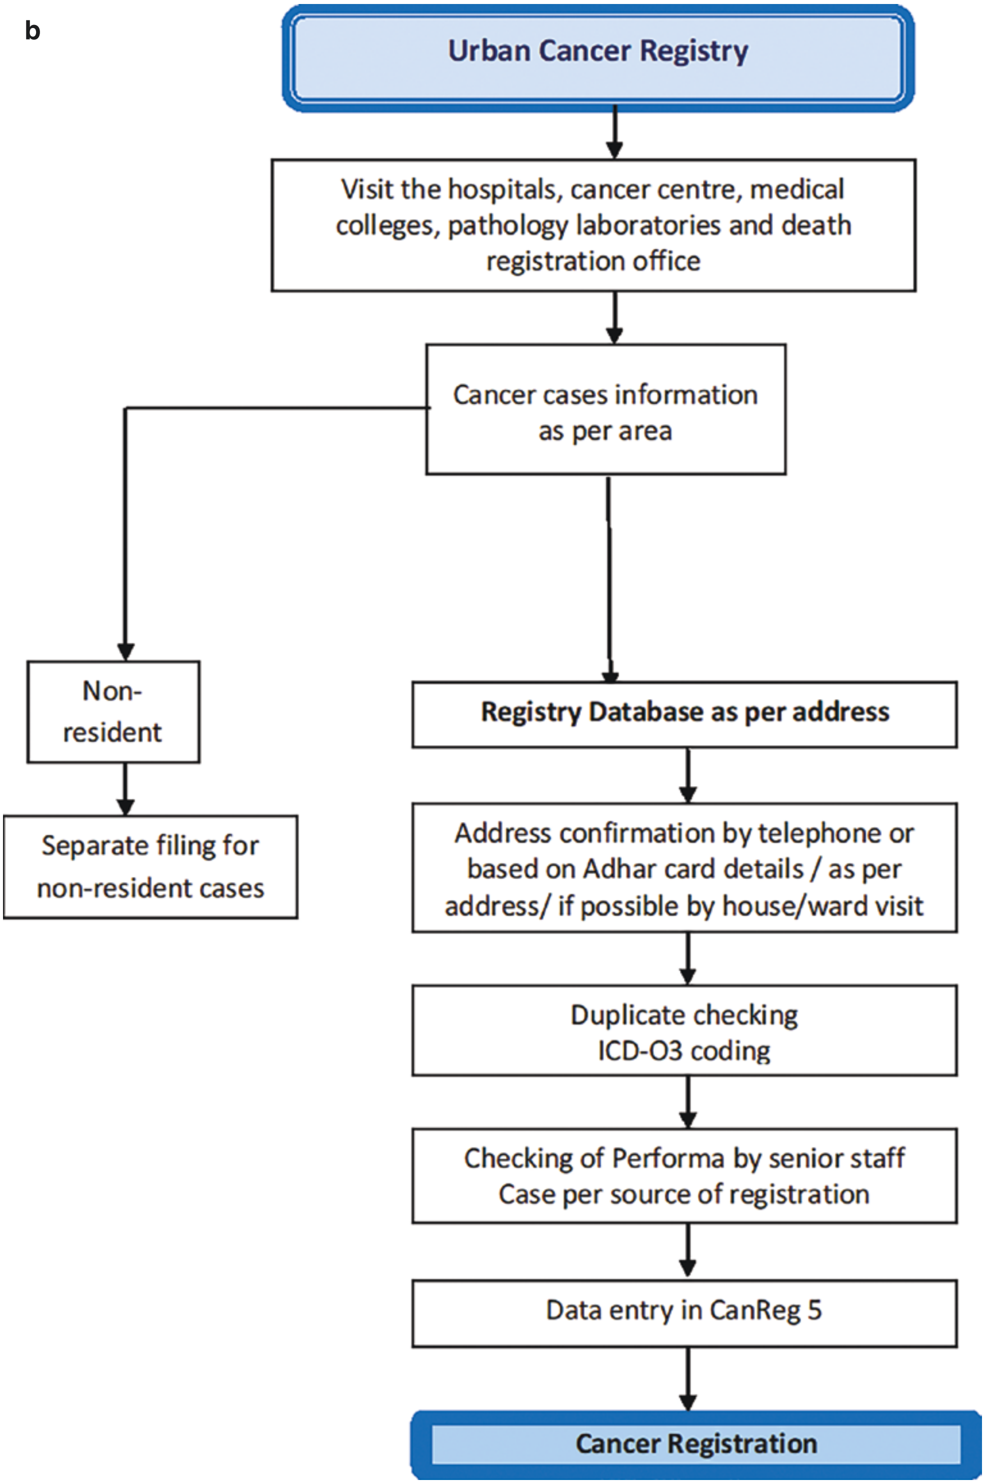
of India. This is because of difficulties encountered while collecting the data from different sources. The major challenges in establishing the registries are lack of a proper documentation system (poor medical records), lack of basic health services (particularly in rural areas), lack of cooperation from different sources of registration to allow collation of data in a given population, and lack of trained personnel in cancer registration.

Cancer registration in India is coordinated mainly by National Cancer Registry Programme (ICMR). At present, there are 36 PBCR and 236 HBCR under National Cancer Registry Programme of India [1]. In addition, the Centre for Cancer Epidemiology at Tata Memorial Centres coordinates 19 PBCR [2–4]. The cancer registries operational in India are summarized in Fig. 2.



a
Rural Cancer Registry
Field staff visit
Visit the hospitals, cancer centre, medical colleges, pathology laboratories and death registration office
Field staff interact with community leaders, (ANM, ASHA workers, PHC workers, Medical officers) (Periodically 6 months)
Obtain information regarding cancer cases, death and prevalent cases in the villages
Cancer cases information as per area
Confirmation of cancer cases by home visit (Residence confirmation)
Interact with patients / relatives with the help of the ASHA worker
Checking of the discharge card / reports available with patients / information regarding treating hospital noting of hospital case number / status updating of old cancer cases
Non-resident
Cancer cases information from the treating hospital
Separate filing for non-resident cases
Registry Database
Separate filing for prevalent cases
Duplicate checking ICD-O3 coding
Checking of Performa by senior staff Case per source of registration
Data entry in CanReg 5
Cancer Registration

Fig. 1 (**a**) Work flow for rural cancer registry. (**b**) Work flow for urban cancer registry



b
Urban Cancer Registry
Visit the hospitals, cancer centre, medical colleges, pathology laboratories and death registration office
Cancer cases information as per area
Non-resident
Separate filing for non-resident cases
Registry Database as per address
Address confirmation by telephone or based on Adhar card details / as per address/ if possible by house/ward visit
Duplicate checking
ICD-O3 coding
Checking of Performa by senior staff
Case per source of registration
Data entry in CanReg 5

Fig. 2 Network of population-based cancer registries in India

2 Cancer Burden in India

The cancer burden in India is estimated by two sources:

1. **GLOBOCAN**: International Agency for Research on Cancer (IARC) maintains an interactive web-based platform to provide global cancer statistics. It is updated from time to time and takes into account data of existing PBCR and extrapolates it to all over India. The GLOBOCAN estimates are based on the weighted/simple average of the most recent local rates of existing PBCR and extrapolated to all over India.
2. **Global Burden of Disease**: As a part of Global Burden of Disease initiative, cancer burden was estimated in India using data from multiple sources, including 42 PBCR and the nationwide Sample Registration System of India. Global Burden of Disease estimated the incidence and mortality from 1990 to 2016 for different states. The estimates of global burden of disease were published in *Lancet Oncology* and are close to estimates made by GLOBOCAN [5].

The GLOBOCAN 2018 estimated 1.1 million new cases of cancers (570,045 male cases and 587,249 female cases) cases in India in the year 2018 [6]. The site-wise estimates for male and females are tabulated in Tables 2 and 3. The leading cancer among males are oral cavity and lung cancer, followed by stomach, colorectal and oesophagus cancer. Among females, breast cancer is the predominant cancer, followed by cervix uteri, ovary, and oral cavity. All the registries in India have shown increase in rates of breast cancer while cervical cancer has shown substantial decrease in last 15 years in urban as well as rural registries. The five most frequent sites in India are tabulated in Table 4.

ASR age-standardized rates

3 Regional Diversity in Cancer Burden and Type

Cancer rates and types differ in India by geographical regions. There are also rural urban differences within the geographical regions. The cancer rates are much higher in most states in North Eastern India. The rates in rural India are much lower than those reported by urban registries. The highest rates are reported by the Mizoram state cancer registry (211.5 per 100,000) while the lowest rates are reported by rural registry of Barshi (40.9 per 100,000).

The cancer rates in different PBCR are shown in Fig. 3, while regional diversity in burden and cancer types is tabulated in Table 5.

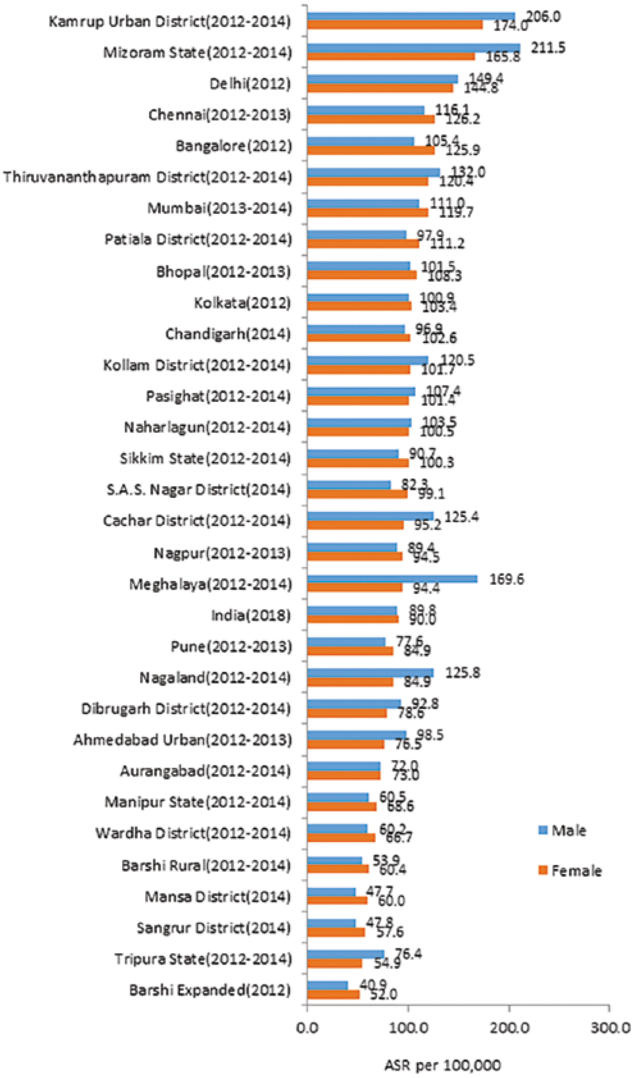

Fig. 3 Age-standardized rates in cancer registries in India—2016

4 Utility of Cancer Registry Data

Cancer registries are essential for developing cancer control strategies. Cancer registries are considered as "Central Nervous System (eyes and ears) of Cancer Control Programme." The cancer registries are useful in:

1. Identification of cancer burden in population and thus guide to requirement of need of primary, secondary and tertiary facilities.
2. Identify most common cancer sites and monitor trends over the year.
3. Evaluate the success of primary and secondary prevention programme.
4. Evaluate success of treatment.
5. Generate hypothesis regarding risk factors of cancer by comparing differences and similarities in incidence rates in different population.

Examples of utilization of registry data are below:

1. **Utility of cancer registry data in building treatment facility and to eliminate fear of cancer**
   There was widespread belief in Punjab that cancer rates were very high in Punjab compared to other parts of India. Tata Memorial Centre, Mumbai thus took up the task of establishing a cancer hospital in Punjab state. PBCR were first established in rural areas, small towns, and big cities of Punjab. Registry data demonstrated that cancer rates are not very high in Punjab compared to other parts of India and provided useful information to build up the cancer hospital as per requirement of the state [7–10].
2. **Evaluating success of primary prevention programme**: In India, there is a huge tobacco control programme. The programme has resulted in reduction in the use of smokeless tobacco. In order to assess the impact of

reduction in use of smokeless tobacco on incidence and mortality over the period of time can only be evaluated by data from cancer registries [11].

3. **Evaluation screening programme**: In Mumbai, a cluster randomized trial was planned to evaluate impact of clinical breast examination on reduction in breast cancer mortality and role of visual inspection with acetic acid in reducing mortality from cervical cancer. The trial was conducted for 20 years to observe effect on mortality. PBCR in Mumbai provided important information on breast and cervical cancer mortality to evaluate its success. Similarly, the government of India has launched a screening programme for breast, cervix and oral cavity cancer in India. The impact of a nation-wide screening programme in reducing mortality for these cancer sites will be evaluated only by good-quality cancer registries [12].
4. **Evaluating changes in cancer pattern in India**: Cancer of cervix uteri was one of the most leading sites of cancer in Mumbai and other parts of India, while breast cancer rates were much lower. With changes in life style and economic transition, there were changes observed in pattern of female cancer, with cervical cancer showing sharp decline in urban and rural areas. The rise of breast cancer was observed by all registries in India over the past two decades. This information is extremely useful in planning prevention and treatment facilities for female cancer [13, 14].
5. **Generating hypothesis**: It was observed by registry data that there is a huge geographical difference in incidence of gall bladder cancer. Gall bladder cancer has high rates in the north and northeast of India, but the rates are lower in western and southern in India. A case–control study was planned by Tata Memorial Centre, Mumbai to evaluate risk factors for this fatal cancer. Factors like history of gallstones and use of contaminated mustard oil were observed as important risk factors, which guided the development of preventive strategies for gall bladder cancer in the high-risk region [15, 16].
6. **Evaluating cancer care**: The registry data have been used to measure population-based survival. This has helped in providing indication of level of cancer in different populations [17].

In India, PBCR covers around 10% of the population in India. Although many more cancer registries are required in order to obtain a more accurate assessment of cancer incidence and mortality, registries so far have provided extremely useful information that has been used by government in planning cancer control.

VIA	Visual inspection with acetic acid
VILI	Visual inspection with Lugol's iodine

1 Principles of Screening

Screening tests are primarily not diagnostic tests. Screening implies and refers to the application of a relatively simple and inexpensive test to an apparently healthy population with no overt signs or symptoms of the disease in question to identify subset of individuals who warrant additional investigation to determine the presence or absence of the particular disease in question [1].

The ultimate objective of screening for a particular disease is to bring down the mortality from that disease among the individuals subjected to the screening test. However, the true benefits of any type of screening have to be assessed by evaluating the cost of administration, its risks and the benefits that may be derived accrued by implementing it in public health programs [2].

Not only that the chosen screening modality should have documented strong evidence from randomized control trials for it being effective in decreasing mortality from cancer, but the potential benefits of organized population-based cancer screening program need to outweigh any potential harms to apparently normal people screened [3].

Thus, the essential minimum requirements for disease control program for population-based screening should be based on the determination of evidence on benefits versus risks and costs of cancer screening as adopted by the World Health Organization, which essentially takes into account (1) disease condition, (2) suitable screening test and (3) health care systems requirements [1, 4, 5].

1.1 Disease Condition

The disease in context should be an important public health problem for control. Cancer incidence or mortality rates need to be assessed for the region to warrant instituting a screening program. There has to be sufficient understanding of the natural history of the disease with recognizable pre invasive clinical phase to estimate the opportune significant window period during which the disease is detectable, and effective treatment can be instituted to justify screening.

There has to be an accepted and effective treatment for the disease if detected in the presymptomatic stage with early treatment offering distinct advantage of reduction in mortality over the late treatment that is given after the development of symptoms.

An evidence-based treatment policy needs to be in place for disease management. Furthermore, the benefits of detecting the disease condition in a few people should outweigh the harms that can occur to people with a false-positive test, including unnecessary invasive investigations and treatment.

1.2 Suitable Screening Test

The chosen screening tests should have high level of accuracy with validated operating characteristics. The screening test must be cost-effective, safe, acceptable and convenient to administer in organized public health program settings with least discomfort and complications for people to participate for sustainable program implementation.

1.3 Health System Requirements

Target population to be screened needs to be clearly defined with respect to age, eligibility and screening intervals. Effective implementation of screening program can be accomplished if it is able to decrease the disease morbidity and mortality in the eligible target population. This requires well established referral network to access quality assured diagnostic services for the screen detected cases with accessible and adequate treatment facilities for those diagnosed with the disease including follow up of individuals treated for the disease.

1.4 Practical Concerns, Harms and Benefits from Screening

Screening programs are initiated by the health systems of the country for healthy individuals to achieve net health benefit for the communities; however, administration of the screening tests to large populations can result in unintended adverse outcomes for some individuals due to false-positive and false-negative test results. Hence, adequate information and communication of likely adverse effects as well as the potential benefits helps informed decision making for participation in the program. Regular process monitoring, evaluation and quality assurance of screening programs are vital to ensure effectiveness of the program implementation.

This chapter explores the evidence for screening effectiveness and the most resource-appropriate relevant cancer screening modalities for screening and early detection of the three most common cancers prevalent in low–middle-income countries (LMICs) like India.

2 Cervical Cancer Screening

An estimated 569,847 new cervical cancer cases and 311,365 deaths were reported worldwide in 2018 with cervix cancer as the fourth most commonly diagnosed cancer and fourth leading cause of cancer related mortality among women worldwide in LMIC countries [6].

India contributed 28% of cervical cancer mortality burden with 87,090 deaths due to cervical cancer. Cervical cancer incidence rates varied across population-based cancer registries (PBCR) in India with a mean age-standardized rate (ASR) of 14.7 per 100,000 (Globocan 2018) [7]. Papumpare district in Arunachal Pradesh (30.2), Aizawl district (28.0) and Mizoram state (23.1) in North East India reported the highest age-adjusted rates (AAR) for cervical cancer [8].

Data examining trends for cervical cancer from six PBCRs in India spanning almost two decades between 1982 and 2003 have reported significant reduction in the incidence of cervical cancer in all registries with 2% mean annual percentage change (MAPC%) over a period of time [9, 10].The decreasing trends in cervical cancer incidence in the absence of an organized screening program has been attributed to improvements in overall education and socioeconomic status of women with associated increase in age of marriage, improvements in genital hygiene and adopting family planning services [11, 12].

Cervical cancer is mostly preventable. Availability and improved access to population-based cervix cancer screening services will help further bring down the incidence and mortality due to cervical cancer in the regions.

2.1 Cervical Cancer Screening Tests

2.1.1 Cervical Cytology

Screening using the conventional Pap cytology, though, had never been rigorously tested in randomized clinical trials; however, conventional cytology-based screening programs in developed countries have reported substantial reductions in cervical cancer mortality [13].

Quality assured pap cytology test is a highly specific, with estimates of the order of 98% to 99%. Several meta-analyses however have reported low Pap cytology sensitivities for the CIN2 and CIN 3 (53% in HIC and 26–65% in LMIC) [14, 15].

Thus, due to the low sensitivity of cytology, the cervical screening benefit to the population comes only with the tests being undertaken and administered regularly at frequent intervals with high screening coverage of women and good quality assurance and monitoring of the program. In LMICs, however, organization of such systematic screening programs is not feasible for economic and socio-demographic reasons besides inadequate infrastructure and quality assurance measures. In fact, introduction of cytology screening programs in the Latin American countries like Brazil and Mexico has not demonstrated reduction in the cervical cancer burden in the region [16, 17].

In the post-HPV vaccine era, with reported nearly 90% reduction in the prevalence of cervical pre cancer lesions and based on the protection offered by the newest nonavalent vaccine there will be a significant reduction in the PPV of cervical cytology [18, 19].

A critical evaluation of the impediments in initiating cervical cytology screening programs in LMICs led to a search for alternative low-cost screening techniques that are operationally feasible and scientifically valid based upon visual inspection of the cervix, i.e., Visual inspection with acetic acid (VIA), visual inspection with Lugol's iodine (VILI) to provide cervical cancer screening services through the public health platform.

2.1.2 Visual Inspection with Acetic Acid (VIA)

VIA is simple, noninvasive and inexpensive visual test, has easy to learn approach, does not require any laboratory setup and is a real-time test with results available immediately, and even nonphysicians can be trained to perform the procedure [20].

VIA has emerged as the most cost effective, operationally suitable screening modality for LMICs with the potential for greater population coverage than other screening approaches. VIA as the most suitable alternative to cervical cytology have been evaluated for its test characteristics in several cross-sectional studies in LMICs. The pooled test characteristic estimates for VIA from the IARC lead multicenter studies conducted across India and Africa have demonstrated sensitivity in the range of 62% to 80% and specificity ranging from 77% to 84% to detect high-grade CIN lesions [21].

In a large cluster randomized trial for VIA conducted in Southern India, VIA was performed by trained nurses and has reported 25% reduction in cervical cancer incidence and 35% reduction in mortality with single round of screening by VIA [22]. Another large cluster randomized study, Mumbai, in Western India, recently reported a significant 31% reduction in cervical cancer mortality with four rounds of biennial VIA screening performed by trained primary health workers. The interobserver variability (kappa) coefficient reported in the study was 0.84 between the primary health workers and an independent examination by expert clinician. This study also reported an almost zero over-diagnosis rate, which is very crucial for overburdened public health systems in LMICs [23].

More recently, Sauvaget and colleagues, after pooling 26 studies from low- and middle-income provided summary estimate of VIA accuracy for sensitivity of 80% (range 79–82%), specificity of 92% (range, 91–92%), PPV of 10% (range 9–10%) and NPV of 99%. Factors such as region, capacity of personnel such as health worker, nurse, or physician undertaking the screening, study duration, screening settings as well as size of study population had no impact on VIA accuracy, demonstrating the overall reliability of VIA screening [19]. Another meta-analysis published earlier had reported sensitivity of VIA at 79% with lower specificity at 85% [24].

In terms of feasibility of administration, VIA test can be performed by a wide range of personnel. Since the test provides immediate results and allows for prompt referral for further diagnostic evaluation. Thus, with effective referral linkages for treatment, VIA can be a most optimal alternative to cytology screening in low-resource countries with high burden of cervical cancer to bring down the incidence and mortality due to the disease.

2.1.3 Human Papilloma Virus (HPV) Testing

Human papillomavirus (HPV) causality for cervical cancer is now been well established and is considered a necessary cause of the disease with HPV 16 and 18 accounting for 70% of cervical cancer cases. Molecular laboratory techniques to detect viral DNA or the mRNA of the E6 and E7 oncoproteins of the target oncogenic HPV types, which are highly sensitive and reproducible, are available and have been recommended in place of cervical cytology for primary cervical cancer screening. This is in addition to other potential uses of HPV testing such as triage of equivocal or low grade CIN and follow-up of women treated for high-grade CIN to determine cure rates [25].

In meta-analyses of cross-sectional studies, the sensitivity of the most commonly used Hybrid Capture 2 (HC2) DNA test was 90.4% to detect CIN2+ and 95.3% to detect CIN3+ respectively; the specificity was however consistently lower than cytology at 86.5% (95% CI = 83.1–89.8%) [26]. Results from a multicenter study in India reported the sensitivity of HPV test varying from 45.7% to 80.9% for detecting CIN 2–3 lesions across the study sites; the specificity ranged between 91.7% and 94.6% and the positive predictive value between 6.7% and 13.7% [27].

A large cluster randomized trial for cervical cancer screening in rural India evaluating VIA, conventional cytology and HPV DNA testing, reported that HPV testing alone was associated with 53% reduction in the number of advanced cervical cancers and 48% reduction in deaths with single round of screening with hrHPV testing compared with the existing standard of care of only opportunistic screening. No reduction in cervical cancer mortality was reported in the groups undergoing screening by cytology despite the strict adherence to the quality control and participant follow up procedures adopted in the study [28].

There is now consistent and robust evidence that HPV DNA detection has 20–45% greater one-time test sensitivity for high-grade CIN than cytology-based methods. HPV DNA testing has some definite advantages over the other tests in that the test being objective, reproducible with high-throughput technologies enabling to process large number of samples at the same time, with some of the test platforms delivering the results in less than 3 h. However, the test still remains unaffordable and expensive for many LMICs. The high negative predictive value (NPV) of HPV testing (nearly 100%) allows extending the screening interval up to 5–10 years. Requirement for lesser number screening rounds translates into consequent savings for the governments that can offset the possibly higher cost of the test compared with cytology [29–31].

With the upcoming HPV DNA detection platforms with the potential to deliver more simplified and point-of-care HPV tests, HPV screening offers the possibility of linking screening to treatment in a single visit, in resource constrained settings. In a randomized screening trial that investigated the acceptability and efficacy of screening women and treating those with positive tests without colposcopy and histological sampling, the study demonstrated that the HPV test screen-and-treat intervention was associated with a 3.7-fold reduction in the cumulative detection of CIN2+ lesions by 36 months against that of VIA which was associated with a 1.5-fold reduction. Thus, for every 100 women screened, the HPV DNA test screen-and-treat strategy averted 4.1 cases of CIN2+ compared to 1.8 cases averted with VIA-screen and-treat strategy [32].

2.1.4 Self-Collected Vaginal Samples

Recent years have added promising results from HPV DNA testing through self-collected samples versus that of health care personnel collected samples, with almost complete preservation of the sensitivity and specificity of the screening method.

Evidence suggests that self-HPV testing is well accepted, can be performed by women with appropriate information and instructions in the privacy of their homes and was found to be more accurate than VIA and also compared favorably with that of clinician-HPV testing for screening of cervical cancer in low-resource settings where there are challenges for women to access health facilities as well as hard to reach remote areas of the region [33, 34].

A pooled analysis of self-collected HPV testing however reported low sensitivity and specificity than testing clinician-collected samples with signal-based assays. By contrast, some PCR-based HPV tests generally showed similar sensitivity on both self-samples and clinician-based samples [35]. Self-HPV testing may complement current screening programs and also offer an opportunity to improve screening coverage in settings that do not have easy access to screening and to reach out to women not likely to participate in the regular screening program [36].

2.2 Conclusion

Both the screening modalities of HPV testing and VIA have proved to be effective in preventing cervical neoplasia and thereby deaths due to cervical cancer in clinical trials. Screening using point of care VIA test to detect precancerous lesions that can be treated cost effectively in single visits would be currently suitable in developing country settings like India. In future when affordable rapid tests for the carcinogenic types of HPV infection become available for use can be the screening tools of choice for implementation in population-based settings [37].

Results from the cost-effectiveness studies conducted across three continents from LMIC of India, Kenya, Peru, South Africa and Thailand indicate that screening approaches requiring minimal visits, including single visit strategies that combined testing and treatment are the most cost effective. Two or three screenings per lifetime, starting around age 35 years, at intervals of 5 to 10 years, with either VIA or HPV testing reduced the lifetime risk of cancer by approximately 25% to 36%, and projected to cost less than 500 dollars per year of life saved [38, 39].

Since many low-resource settings do not have optimal infrastructure and capacity for cervical cancer treatments, screening and early detection through organized screening program with timely treatment of cervical precancerous lesions before they become invasive with high screening coverage are necessary for reducing morbidity and mortality due to cervical cancers. Health policymakers, public health program managers and health professionals responsible for recommending the most suitable country-level cervical cancer prevention and screening strategies for public health program implementation need to design and integrate comprehensive cervical cancer prevention and control within the larger initiative for the control of noncommunicable diseases utilizing and training the existing manpower and health infrastructure resources with in the country.

3 Breast Cancer Screening

Breast cancer is the most common cancer and most common cause of cancer related death among women globally and in India. An estimated 2,088,849 new breast cancer cases were diagnosed globally in 2018, accounting for 24.2% of all female cancers and the fourth leading cause of death due to cancers in females with nearly 626,679 women deaths due to breast cancer [7, 40]. With 162,468 new cases, the age-standardized incidence rate for breast cancer was reported at 24.7 per 100,000 in India [7].

Incidence of breast cancer has been rising at the rate of almost 5% per year has been observed among urban women in low- and middle-income countries (LMICs), where rates were historically low. The rising trends have been attributed to life style changes in the childbearing patterns, increased adoption of western lifestyles and dietary choices in urban and semiurban regions. Mortality rates are continuing to remain high in LMICs since majority of the women continue to present in the late-stage of the disease largely due to very limited screening, diagnostic and treatment capacities in these regions [41, 42].

Thus, implementing appropriate screening measures for detecting asymptomatic disease and early diagnosis of symptomatic disease, which is further facilitated by appropriate treatment, are essential components of breast cancer control strategies.

3.1 Mammography

Mammography for breast cancer screening has been the most widely used screening modality, in high-income countries with evidence of benefit for women aged 40 to 74 years. Other screening tools such as clinical breast examination (CBE) and breast self-exam (BSE) have also been evaluated across but are of uncertain benefit. Technologies such as ultrasound, magnetic resonance imaging, tomosynthesis and molecular breast imaging are being evaluated, usually as adjuncts to mammography.

The evidence for efficacy of mammographic screening was established mainly from randomized controlled trials (RCTs), in which women were randomized to mammographic screening at regular intervals or no screening. Based on the outcomes of these trials, IARC estimated a 25% reduction in breast cancer among women between age 50 and 69 years and 19% in women age 40 and 49 years. The results were consistent across studies among older women but were inconsistent among women in their forties [43–49].

Evidence suggests that mammography screening performed every 12 to 33 months is effective in decreasing breast cancer mortality. Benefit from screening by mammography is largely due to regular biennial screening. The estimates for women who need to be screened to save a life are 1904 for ages 39–49; 1339 for ages 50–59 and 377 for ages 60–69, respectively [43].

Accuracy of screening mammography is largely dependent two main factors, patient factors related to age, breast density use of hormone replacement therapy and factors related to radiology instrumentation along with training of the radiologist whose performance varies substantially depending on the training and level of experience [47, 48].

Also, the demonstrated benefit of mortality reduction by mammography screening is likely to be outweighed by the risk of harm due to false-positive findings or the potential for overtreatment of nonaggressive biologically favorable early-stage disease [49, 50].

Harms from screening vary with patient age, life expectancy and tumor type (ductal carcinoma in situ and/or invasive) [51, 52]. Though the estimates of over diagnosis vary widely, from less than 5% to more than 50%, nearly 54% of the overall breast cancers detected by screening mammograms are estimated to be due to overdiagnosis [53]. In the follow-up of the long-term CNBSS and well-conducted excess incidence studies in the United States [54] and Scandinavia [55, 56] at least 20% of screen-detected breast cancers were overdiagnosed.

Though women across all age group subjected to mammography screening witness false-positive test results, overdiagnosis and unnecessary earlier treatment; however, false-positive results are more common among women aged 40 to 49 years, whereas overdiagnosis is a greater concern for women in the older age groups [57], On an average, 10% women are likely to be recalled after each screening mammography for further testing, and only 5 of the 100 women recalled are likely to have cancer [58].

According to the Cochrane Review, assuming that mammography screening reduces breast cancer mortality by 15% with rates for overdiagnosis and overtreatment at 30%, it means that for every 2000 women invited for screening throughout 10 years, one will avoid dying of breast cancer and 10 healthy women, will receive unnecessary treatment, who otherwise would not have been diagnosed if they had not been screened. Also another 200 women will be subjected to psychological distress and uncertainty for extended duration because of false-positive findings. With substantial advancements in breast cancer treatment modalities and greater awareness toward early detection of breast cancers since the trials were carried out, it is most likely that the absolute benefit of screening today is much smaller than in the trials. Recent observational studies have shown more overdiagnosis than in the trials and nonsignificant or no reduction in the incidence of advanced cancers with breast cancer screening [49].

Cost-effectiveness analysis carried out by the WHO and partners in various middle-income countries showed that mammography screening was not cost-effective for a lower-middle income country [59].

Since mammographic screening requires considerable infrastructure and costs, screening with clinical breast examination (CBE) and breast self-examination (BSE) has been under consideration in LMICs.

3.2 Clinical Breast Examination (CBE)

Until recently, two randomized control trials assessing CBE alone as a screening tool, were on-going in India [60, 61], out of which results of the Mumbai Study, led by Tata Memorial Centre, which is one of the largest and oldest trial with biennial CBE that was offered four times in one arm versus no screening in the other arm in its final study results has reported a significant reduction in mortality of nearly 30% in women aged ≥50. No significant reduction in mortality was seen in women younger than 50 years [61].

CBE earlier has been used in conjunction with mammography in one Canadian trial, and as the comparator modality versus mammography in another trial. Based on the 25-year follow-up from the Canadian National Breast Screening Study (CNBSS), an RCT of breast cancer screening [62], annual mammography does not reduce breast cancer mortality beyond that of CBE or usual care.

CBE accuracy depends on the provider skills with optimal training in using proper standard technique, and the measure of its sensitivity and specificity, therefore, has bearing on harms due to false-positive results leading to additional testing and anxiety as well as false-negative results with potential for false reassurance and delay in cancer diagnosis. Specificity of CBE in women aged 50 to 59 years was 88% to 99%, yielding a false-positive rate of 1% to 12%. Sensitivity is higher with longer duration, proper techniques and quality training by the trained personnel [63].

As per the current evidence, CBE may be more efficacious, practical and cost-effective option in LMICs, since it can be performed by nonmedical, trained health care workers and combined with timely effective treatment, can further bring down breast cancer mortality at the population level.

3.3 Breast Self-Examination (BSE)

BSE is the examination performed regularly by the women themselves after receiving appropriate instructions to perform systematic examination of the entire breast for a lump or other change in the breast that is suggestive of cancer. Most evidence for the efficacy of BSE comes from two randomized trials from Saint Petersburg [64] and Shanghai [65] where BSE was compared with usual care (no screening activity) and has not been shown to reduce breast cancer mortality [66, 67].

In both of the completed BSE trials, the group that received instructions to perform BSE reported more benign breast lesions than in the control groups suggesting that formal instruction to perform BSE leads to more breast biopsies and diagnosis of more benign breast lesions with biopsy rate of 1.8% among the study population compared with 1.0% among the control group [66]. Both the IARC working group and the US Preventive Services Task Force concluded that the efficacy of BSE remains to be proven [68].

3.4 Ultrasonography

Ultrasonography is not a primary screening modality, its primary role lies in the diagnostic evaluation of palpable or masses identified on mammography. A consensus statement by the European Group for Breast Cancer Screening on screening of breast cancer using ultrasound examination concluded that ultrasound is an adjunct to mammography and clinical examination in the further assessment of both palpable and nonpalpable breast abnormalities. At the population level, screening of asymptomatic women by the use of ultrasound was associated with very high rates of both false-positive and false-negative results. Hence, they found little evidence to support the use of ultrasound in population breast cancer screening at any age [64]. Less than 3% of women with lump will ultimately be found to have breast cancer, in the setting of normal mammography and ultrasonography [65, 69–71].

3.5 Conclusion

Resource constrained settings, where mammography screening is not cost-effective or feasible and majority of women are diagnosed in late stages with breast cancer should optimize the available resources for ensuring access to women with symptomatic lesions to health services for early diagnosis and treatment. With the recent evidence form the Mumbai Breast cancer screening study, low-cost screening approaches such as CBE, seems to be a promising approach for developing country settings [61, 72].

In addition to the LMIC's barriers of literacy and education among women about awareness of breast cancer, its risks, perception and misconceptions toward diseases in general need special focus. Development of culturally relevant, appropriate local education programs for Breast health awareness emphasizing value and benefits of early detection in improving breast cancer outcome and saving lives are critical to improving population coverage and participation in early detection programs [73].

4 Oral Cancer Screening

Globally, lip, oral cavity cancers accounted for an estimated 354,864 new cases and 177,384 deaths in 2018. World age-standardized incidence rate (ASIR) per 100,000 for Lip, oral cavity cancer as per the GLOBOCAN 2018 estimates were 4.0 with age-standardized death rate (ASDR) rates of 2.0. With 119,992 new cases, India reported lip, oral cavity cancer with ASIR of 9.1 for both sexes combine and 13.9 among males. Lip and oral cavity cancers thus were the top-ranked cancers among males and the second highest malignancy in both the sexes with equally high mortality rates of 9.2 (ASDR) [74]. In India, 5-year survival is estimated at less than 35% [75].

Any form of tobacco use and excessive alcohol use are the major risk factors for oral cavity cancer. The relatively high prevalence of oral cancer in India is mainly attributed to the use of the smokeless tobacco products and consumption of betel quid with or without tobacco [76, 77]. Human Papilloma Virus (HPV) has been shown to be another independent risk factor for oral squamous cell carcinomas (OSCC) of the base of the tongue, tonsils, pharynx and larynx [78–81].

Despite the ease of performing the oral cavity inspection during routine physical and dental examination, oral cancers are still detected in very advanced stages of disease resulting in poor prognosis. Early detection of oral pre cancer lesions can significantly reduce the currently high mortality rate attributable to oral cancer. Oral cancer has a well-documented long preclinical phase, starting with an oral preinvasive lesion (OPL) consisting of potentially malignant disorders such as leukoplakia, submucous fibrosis, erythroplakia, that progresses through the increasing degrees of dysplasia, and finally develops into invasive oral squamous cell carcinoma (OSCC). These OPL can be clinically detected through careful visual inspection and palpation of the oral cavity. Early detection would not only significantly improve the cure rate and thereby reduce mortality, but it would also lower the cost and morbidity associated with treatment of late stage oral cancers [82].

Robust evidence is needed to select the most suitable screening tool with required criteria of being highly specific and sensitive, cost effective and therefore economically viable for implementation in population screening programs.

4.1 Oral Cancer Screening Tests

4.1.1 Oral Visual Inspection (OVI)

A conventional oral visual inspection (OVI) of the oral cavity, using normal (incandescent) light, has long been the standard method for oral cancer screening. The UK working group on screening for oral cancer and precancer in the 1990s had concluded that the most suitable screening for oral cancer and precancer is a thorough and systematic examination of the oral cavity conducted with good lighting [83]. OVI has been widely evaluated for its efficacy, ease of administration and acceptability to detect oral precancerous lesions and cancer including cost-effectiveness studies in low-income settings in reducing oral cancer mortality [84–92].

OVI is a subjective test and being provider dependent, its test performance in detecting precancerous lesions and early asymptomatic oral cancers had sensitivities ranging from 60% to 97% and specificity ranges from 50% to 99% [84–87]. A meta-analysis reported an overall sensitivity of 0.85 (95% CI 0.73, 0.92) and specificity of 0.97 (95% CI 0.93, 0.98) indicating a satisfactory test performance for an oral examination [88].

Trials in India of oral visual inspection to detect lesions by trained health workers have shown pooled sensitivity of 87.90% and specificity of 92.05% [89–91]. A significant 34% reduction in oral cancer mortality was demonstrated among a high-risk group of tobacco or alcohol users following three rounds of oral visual screening in a cluster-randomized controlled trial in India [91]. The same study from India with 15-year follow-up results found sustained reduction in oral cancer mortality, There was a 81% reduction in oral cancer mortality (95% CI 69–89%) in tobacco and/or alcohol users complying with all four rounds of screening [92].

This was the first evidence from a cluster randomized control trial to provide the efficacy of an oral cancer screening program, suggesting good evidence for oral visual examination in reducing mortality rate of oral cancer in high-risk individuals. Population-based screening program could result in diagnoses of oral cancer at an earlier stage of disease with improved survival rates [93]. The cost-effectiveness study that used data from a randomized clinical trial in India provides evidence that oral cancer screening with oral visual inspection by trained health care workers can be administered under U.S. $6 per person in a screening program. The incremental cost per life-year saved was U.S. $835 for the all-screened population and U.S. $156 in the high-risk population using tobacco, indicating cost-effectiveness of screening even in LMIC settings [94].

Although OVI could be considered as an effective screening test, there are still many limitations with this approach since the vast majority of the precancer lesions detected are benign and a very small proportion of lesions are progressive or become malignant. Thus, since OVI cannot discriminate between potentially premalignant lesions from lesions not likely to progress to cancer, the potential harms of oral visual screening therefore include requirement of additional diagnostic investigations, with added burden on health care system for conducting incisional or excisional biopsy leading to detection and treatment of biologically insignificant conditions that may have no impact on oral cancer incidence.

4.1.2 Mouth Self-Examination and Other Screening Methods

Mouth self-examination (MSE) using a mirror has been evaluated as a screening test in some studies [95–97]. However, MSE achieving reductions in oral cancer mortality is not known. MSE was evaluated in a study involving 34,766 subjects in India and was found to have low sensitivity of 18%, while the specificity was 99.9% [98].

There is currently insufficient evidence to recommend the use of any other oral screening tests, such as toluidine blue staining, chemiluminescence, tissue fluorescence imaging, fluorescent spectroscopy, salivary analysis and oral cytology for primary screening of oral cancer [93, 99–101].

A multifaceted approach that integrates primary prevention strategies for tobacco and alcohol control with appropriate health education including tobacco cessation and secondary prevention, focused on high-risk individuals, are likely to be cost-effective and affordable in LMICs. At the same time, investing in health services to provide screening and early diagnosis services, and timely treatment for those diagnosed with invasive cancer will help attain the goal of decreasing the burden of oral cancer along with addressing disparities and inequalities in providing the population level services in the regions where it is most needed.

5 Other Cancers

5.1 Prostate Cancer Screening

Prostate cancer is the second most common cancer among men globally and accounts for 15% of all the cancers in men. The incidence is noted to be high in the more developed regions, because of widespread usage of prostate-specific antigen (PSA) testing and subsequent biopsy. In India, there are 19,095 new cases of prostate cancer annually accounting for 4% of all cancers among men [102].

The screening tests for prostate cancer include the digital rectal examination (DRE) and the PSA blood test. Thereafter the diagnostic confirmation is carried out by transrectal ultrasound (TRUS) guided biopsy. Cochrane Review [103] included meta-analysis of five studies [104–108] that did not demonstrate any statistically significant reduction in prostate cancer specific mortality risk ratio (RR) 1.00, 95% confidence interval (CI) 0.86–1.17. Also meta-analysis of the two low risk of bias studies, the European Randomized Study of Screening for Prostate Cancer (ERSPC) [104] and the US Prostate, Lung, Colorectal and Ovarian (PLCO) Cancer Screening Trial [106] indicated no significant reduction in prostate cancer-specific mortality (RR 0.96, 95% CI 0.70–1.30). Only one study (ERSPC) reported a 21% significant reduction of prostate cancer-specific mortality in a prespecified subgroup of men aged 55 to 69 years [104].

The independent role of DRE has not been evaluated till date. Prostate cancer screening is associated with harms of over diagnosis and overtreatment due to high rate of false-positive results for the PSA test. All these result in subsequent biopsies and harms associated with it, like infection, bleeding and pain. Since any reduction in prostate cancer-specific mortality may take up to 10 years to accrue [103], it has been recommended that men having life expectancy of less than 10 to 15 years should be informed about uncertainties, risks and potential benefits associated from screening for prostate cancer. The current American Cancer Society guidelines [109] recommend that prostate cancer screening should not occur without an informed decision-making process. Men at average risk should receive this information beginning at age 50 years. Men in higher risk groups should receive this information before age 50 years.

5.2 Lung Cancer Screening

Globally, lung cancer is the most common cancer and cause of cancer related death among men as well as among both sexes combined together [110]. The majority of lung cancer cases are attributed to cigarette-smoking and have the highest mortality rate of all cancers. However, early-stage nonsmall cell lung cancers (NSCLC) have been reported to have better prognosis and which can be treated with surgical resection [111, 112].

Most cases of lung cancer present at advanced stages. Previous studies have investigated the role of screening for the detection of preclinical disease [113–115] with chest X-ray screening with or without sputum cytology. Most of the studies were focused on high-risk smokers and have so far concluded that early detection of lung cancer does not improve disease-specific mortality [116, 117].

Low-dose computed tomography (LDCT) for early stage detection of lung cancer has been studied in the recent years. It is found to be more sensitive testing modality than the chest radiography [118–120]. A large uncontrolled study demonstrated ability of LDCT to detect lung cancers at an early resectable stage [121]. The North American National Lung Screening Trial (NLST) the largest trial (n = 53,454) compared annual LDCT screening with chest radiography. In this study, annual screening with LDCT was associated with a significant reduction in lung cancer mortality among high-risk individuals (RRR = 20%, P = 0.004) aged 55 to 74 years with 30 pack-years or more of smoking. The study also reported reduction in all-cause mortality in the LDCT screening group compared with the chest x-ray group (RR 0.94, 95% CI 0.88–1.00, P = 0.04) [122].

The NLST results showed a sensitivity of 93.8% and specificity of 73.4% for LDCT [123]. Routine LDCT screening incurs the harms of false-positive findings with unnecessary workup, intervention and exposure to radiation.

The US Preventive Services Task Force (USPSTF) has recommended annual lung cancer screening in adults aged 55 to 80 years with LDCT, who have a history of 30-pack-years of smoking who currently smoke or have quit within the past 15 years [111]. The American Cancer Society since 2013 began recommending screening for lung cancer with

LDCT in high-risk patients who meet the NLST criteria [124].

There is currently insufficient data on the cost effectiveness of lung cancer screening that account for the frequency of screening, the benefits and harms (such as false-positives and overdiagnosis) to provide any recommendations for large-scale population screening programs. According to the Cochrane Review, screening with either annual plain chest radiography in smokers and nonsmokers, or more frequent chest radiography screening in smokers and ex-smokers, is not effective at reducing lung cancer mortality and hence not recommended for clinical practice [122].

5.3 Colorectal Cancer Screening

Adenocarcinoma of the colon and rectum (colorectal cancer, CRC) globally, colorectal cancers are the third most common cancers for both sexes put together. In India, colorectal cancers are the fourth most common cancers among men and the third most common cancers among women [125].

Screening tests for colorectal cancer screening involve fecal occult blood testing (FOBT) like guaiac fecal occult blood test (gFOBT), fecal immunochemical test (FIT), sigmoidoscopy and colonoscopy. All the above modalities are effective in reducing mortality, through detection and removal of adenomatous polyps and treatment of early-stage cancer. Modeling studies provide evidence to suggest that population screening programs between the ages of 50 and 75 years using any of the three screening modalities will be equally effective in terms of life-years gained [126].

Cochrane review suggests that FOBT screening reduces the risk of colorectal cancer mortality. However, no difference in all-cause mortality between the screened and non-screened populations was reported [127].

The USPSTF recommends screening for colorectal cancer using fecal occult blood testing, sigmoidoscopy or colonoscopy in adults, beginning at age 50 years and continuing until age 75 years. The following screening interval are suggested: (1) high-sensitivity fecal occult blood testing annually, (2) sigmoidoscopy every 5 years combined with high-sensitivity fecal occult blood testing every 3 years and (3) screening colonoscopy at 10 years interval [128].

The risks and benefits of these screening methods largely vary with minimal harm for fecal tests to the use of invasive modalities like sigmoidoscopy or colonoscopy adopted initially or in the evaluation sequence [129]. Potential harms arise from additional diagnostic procedures for lesions found incidentally, which may have no clinical significance. The risks for perforation associated with screening CT colonography in research settings are estimated to be 0 to 6 per 10,000 CT colonography studies [130]. Due to low incidence rates there is no recommendation for routine screening for CRC in India.

Part III

Hematological Malignancies

Adult Lymphoblastic Leukemias

Hasmukh Jain, P. G. Subramanian, Jayashree Thorat,
Raajit Chanana, Swaratika Majumdar,
Rushabh Kiran Kothari, and Rajesh Bollam

Abbreviations

ALL	Acute lymphoblastic leukemia
AML	Acute myeloid leukemia
APML	Acute promyelocytic leukemia
APTT	Activated partial thromboplastin time
ATRA	All-trans-retinoic acid
CLL	Chronic lymphocytic leukemia
CML	Chronic myeloid leukemia
CR	Complete remission
HCL	Hairy cell leukemia
HDAC	High-dose cytarabine
MPO	Myeloperoxidase staining
MRD	Minimal residual disease
NSE	Nonspecific esterase
PS	Peripheral smear
PT	Prothrombin time
TT	Thrombin time
WBC	White blood cell

1 Acute Myeloid Leukemia

Acute myeloid leukemia (AML) is a neoplastic disease resulting from the uncontrolled clonal proliferation of myeloid precursor cells that infiltrates the blood, bone marrow and other tissues. Resultant disruption of normal haematopoiesis leads to infection and bleeding. Early and risk adapted treatment are crucial in the management of AML. Overall prognosis remains guarded with 5-year survival rate ~30% [1].

1.1 Incidence and Epidemiology

SEER database reports an incidence of 4.3 per 100,000 persons/year. No prevalence data is available from India.

Data from TMH, Mumbai, in a series of more than 2500 patients with acute leukemia, attributed 38.3% of all leukemia to be AML of which 75% were adults [2, 3]. There is an increased male preponderance and the median age of presentation is 40 years [4].

Risk factors for developing AML:

1. Genetic syndromes specially those involving DNA repair, bone marrow failure syndromes, Li Fraumeni, Downs syndrome, *RUNX1* mutation and Klinefelter's syndrome.
2. Radiation exposure.
3. Smoking.
4. Prior therapy with alkylating agents, 5–7 years post therapy, typically preceded by myelodysplastic marrow while topoisomerase II inhibitors have no preceding MDS and develop AML rather rapidly (within 2 years of therapy).
5. Antecedent hematological malignancies specially MDS and chronic proliferative disorders (polycythemia vera, myelofibrosis and essential thrombocythemia) can contribute up to 15% of adult AML (>60 years) [5].

1.2 Clinical Presentation

1. Marrow failure/infiltration: bone pain, fatigue and dyspnoea related to anemia, infections especially perianal, pulmonary and cutaneous sites, and bleeding.
2. Hyperleukocytosis: altered sensorium, headache, dyspnoea and hypoxia.
3. Fever, weight loss, hepatosplenomegaly, lymphadenopathy (AML M5).
4. Extramedullary deposits (chloromas): cutaneous nodules, periorbital swelling, gum hypertrophy (AML M5).

1.3 Diagnosis and Classification

Chiefly, AML is classified by two systems namely, FAB and more recently, WHO as tabulated below.

WHO 2008 [6] classification is more complex involving cytogenetic and molecular typing of leukemia into 25 different types (Table 1).

1.4 Investigations

1. Complete blood count (CBC) and peripheral smear (PS)
2. Cytochemistry—Myeloperoxidase staining (MPO), non-specific esterase (NSE)
3. Bone marrow examination—Aspirate and biopsy. Bone marrow biopsy is essential in all cases as presence of clusters of blasts is also diagnostic of AML
4. Immunophenotyping—Flow cytometry

Mandatory—The markers in bold are lineage defining markers

- Immaturity marker—CD45, CD34, HLA-DR
- Myeloid Cells—CD13, CD33, CD117, CD11b, CD15, **AMPO**
- Monocytic Markers—CD14, CD36, CD64, CD11c
- Megakaryocytic—**CD41, CD61**
- Erythroid—CD105, CD71, CD235a
- Plasmacytoid dendritic cells—high expression of **CD123 and HLA-DR**

5. Cytogenetics
   (a) Fluorescent in situ hybridisation (FISH) for risk stratification as shown in Table 2
   (b) Conventional karyotyping—For detecting complex abnormalities and monosomal karyotype
6. Molecular testing
   (a) *NPM1* and *CEBPA* mutations
   (b) *FLT3* internal tandem duplication (*FLT3*-ITD)
   (c) Next generation sequencing if available for *RUNX1*, *ASXL1* and *TP53* mutation, etc.

Table 1 2008 WHO classification with 2016 modification

I	**AML with recurrent genetic abnormalities**	
	1	AML with t(8;21)(q22;q22.1); RUNX1-RUNX1T1 (AML1-ETO)
	2	AML with inv(16)(p13.1q22) or t(16;16)(p13.1;q22); CBFB-MYH11
	3	APL with PML-RARA and variant translocations
	4	AML with t(9;11)(p21.3;q23.3); MLLT3-KMT2A
	5	AML with t(6;9)(p23;q34.1); DEK-NUP214
	6	AML with inv(3)(q21.3q26.2) or t(3;3)(q21.3;q26.2); GATA2, MECOM
	7	AML (megakaryoblastic) with t(1;22)(p13.3;q13.3); RBM15-MKL1
	8	AML with mutated NPM1
	9	AML with biallelic mutations of CEBPA
	a	AML with mutated RUNX1 (provisional)
	b	AML with BCR-ABL1 (provisional)
II	**AML with myelodysplasia-related changes**	
III	**Therapy-related myeloid neoplasms**	
IV	**AML, NOS has the following entities**	
	1	AML with minimal differentiation
	2	AML without maturation
	3	AML with maturation
	4	Acute myelomonocytic leukemia
	5	Acute monoblastic/monocytic leukemia
	6	Pure erythroid leukemia
	7	Acute megakaryoblastic leukemia
	8	Acute basophilic leukemia
	9	Acute panmyelosis with myelofibrosis
V	**Myeloid sarcoma**	
VI	**Myeloid proliferations related to Down syndrome**	
	1	Transient abnormal myelopoiesis (TAM)
	2	Myeloid leukemia associated with Down syndrome
VII	**Blastic plasmacytoid dendritic cell neoplasm**	
VIII	**Acute leukemias of ambiguous lineage**	
	1	Acute undifferentiated leukemia
	2	Mixed phenotype acute leukemia (MPAL) with t(9;22)(q34.1;q11.2); BCR-ABL1
	3	MPAL with t(v;11q23.3); KMT2A rearranged
	4	MPAL, B/myeloid, NOS
	5	MPAL, T/myeloid, NOS

Reference: Daniel A. Arber, Blood (2016)

Diagnosis is established when marrow blast count of >20% except for AML with there current genetic abnormalities t(15;17), t(8;21), inv(16), or t(16;16).

Flow cytometry of bone marrow aspirate or immunohistochemistry on biopsy can subtype AML (see Table 2). Cytogenetic and molecular typing of AML is listed in Table 3.

1.5 Evaluation and Risk Stratification

Apart from tests required for diagnosis, laboratory tests for organ function (liver and renal function), TLS parameters (serum electrolytes including phosphorus and calcium) and

Table 2 ELN 2017 risk stratification

Risk category	Genetic abnormality
Favorable	t(8;21)(q22;q22.1); *RUNX1-RUNX1T1*
	inv(16)(p13.1;q22) or t(16;16)(p13.1;q22); *CBFB-MYH11*
	Mutated *NPM1* without *FLT3*-ITD or with *FLT3*-ITD (<0.5)
	Biallelic mutated *CEBPA*
Intermediate	Mutated *NPM1* and *FLT3*-ITD$^{\text{high}}$[a]
	Wild-type *NPM1* without *FLT3*-ITD or with *FLT3*-ITD$^{\text{low}}$[a] (without adverse-risk genetic lesions)
	t(9;11)(p21.3;q23.3); *MLLT3-KMT2A*[b]
	Cytogenetic abnormalities not classified as favourable or adverse
Adverse	t(6;9)(p23;q34.1); *DEK-NUP214*
	t(v;11q23.3); *KMT2A* rearranged
	t(9;22)(q34.1;q11.2); *BCR-ABL1*
	inv(3)(q21.3q26.2) or t(3;3)(q21.3;q26.2); *GATA2,MECOM(EVI1)*
	−5 or del(5q); −7; −17/abn(17p)
	Complex karyotype[c], monosomal karyotype[d]
	Wild-type *NPM1* and *FLT3*-ITD$^{\text{high}}$[a]
	Mutated *RUNX1*[e]
	Mutated *ASXL1*[e]
	Mutated *TP53*[f]

Reference: Hartmut Dohner, Blood (2017)

viral markers (anti-HIV/anti HCV/HBsAg/anti HBcIgG) are also performed. Baseline NCCT thorax is preferred to assess for fungal infection prior to starting therapy. ECHO and ECG in all patients is required as all receive anthracycline-based chemotherapy. Peripherally inserted central catheters (PICC) is preferred for long-term venous access.

1.6 Management of AML

1.6.1 Supportive Care for AML

Nearly 30% of the patients present with infection at diagnosis [4]. Most common source of infection are blood stream, mucosal especially perianal site, skin/soft tissue and lung. Though quinolone prophylaxis is recommended [7], each institute may decide antibiotic prophylaxis as per sensitivity pattern. In our institution we do not use antibiotic prophylaxis. All patients with neutropenia (disease- or therapy-related) are at risk of fungal infections. All patients must receive antifungal prophylaxis. We use posaconazole 5 mL (200 mg) thrice daily with weekly drug monitoring to maintain appropriate drug levels. Hand washing (patient and care givers), personal hygiene (using antibiotic body wipes thrice daily and bathing) and dental care is mandatory. All patients at risk of HBV reactivation must receive prophylaxis with entecavir/lamivudine.

Use of myeloid growth factors in the induction period may increase leukemic blasts and delay platelet recovery but it reduced the duration of neutropenia by 2–5 days. Post consolidation GCF is routinely used until neutrophil recovery.

Platelet and packed cell transfusions is required throughout induction. At least two granulocyte donors should be screened at the start of induction. HLA typing should be done in intermediate and high-risk patients.

1.7 Treatment of AML

Therapy of AML is divided into two parts, i.e. induction and consolidation. All patients with intermediate or adverse risk category should be evaluated for allogeneic stem cell transplant (HSCT).

Fitness for intensive induction chemotherapy is determined by age (<65 years) and factors like infections and comorbidities. Induction regimens most commonly is “3+7” that is 3 days of an intravenous anthracycline: daunorubicin at a dose of at least 60 mg/m^2 or idarubicin 12 mg/m^2; or mitoxantrone 12 mg/m^2, and 7 days of continuous infusion cytarabine (100–200 mg/m^2) through peripherally inserted intravenous catheter.

Consolidation therapy is given to those who have attained morphological remission after induction. High-dose cytarabine (HDAC) at 2000 mg/m^2 twice daily (total of 6 doses) is given over 5 days for 3–4 cycles. These patients are at high risk of neutropenic infections and require GCSF support and clinical evaluation till count recovery.

Consolidation with allogeneic HSCT should be done in patients with intermediate/adverse risk factors.

In FLT3/ITD, Tab. Midostaurin 50 mg BD from day 8 to day 21 of induction, during HiDAC day 8–day 21 of each cycle.

Maintenance 50 mg BD 14 days of 28 days (start after day 35, after recovery post-cycle 3 HIDAC) for 12 months. To maintain ANC >1000, plt count >1 lakh should be given [8].

1.7.1 Treatment of AML in Elderly Patients

AML in elderly patients is usually a high risk (therapy-related, secondary to MDS or associated with poor-risk cytogenetic abnormalities). Patients more than 65 years or who are unfit for intense chemotherapy can be given treatment as below depending on their general condition:

1. Hypomethylating agents like azactidine or decitabine + BCL2 inhibitor venetoclax

2. SA Hypomethylating agent
3. CPX-351 (liposomal cytarabine + daunorubicin in 5:1 ratio)

Relapsed/refractory AML have poor prognosis. They should be evaluated for early allogenic HSCT. Re-Induction with intermediate-dose cytarabine, FLAG-IDA (fludarabine/cytarabine/idarubicin) or CLAG (cladribine/cytarabine) with GCSF are common salvage regimens.

1.8 Response Assessment and Monitoring

Response evaluation with bone marrow aspirate and biopsy is done usually on day 21 post induction by when there is evidence of peripheral count recovery. Complete remission (CR) is defined when marrow blast <5%, no extramedullary disease (if present at baseline), regression of splenomegaly, recovery of counts, ANC >1000/mm^3 and platelet count ≥100 × 10^9/L. Minimal residual disease (MRD) is assessed using flow cytometry and should be <0.1%. Cytogenetic or molecular abnormality should also be assessed post induction. If MRD is positive, then bone marrow examination is repeated after first consolidation. Primary refractory AML is diagnosed when bone marrow is not in remission after two courses of induction treatment.

1.9 Prognosis and Outcomes

The expected outcomes in AML are influenced by various factors, with an average 5-year overall survival of 40–50%.

1.10 Summary and Practice at TMH (See Table 3)

Table 3 Cytogenetic and molecular typing of AML

Diagnosis	Bone marrow aspirate-morphology, flow cytometry, cytogenetic and next generation sequencing and biopsy
Induction	"3+7" 3 days of an IV daunorubicin 60 mg/m^2; 7 days of continuous infusion cytarabine 100 mg/m^2 through PICC
Consolidation	Three cycles of high-dose cytarabine (HDAC) at 2000 mg/m^2 twice daily day 1, 3, 5 every 21 days
Relapsed AML	CLAG regimen followed by HSCT or if HSCT is not feasible to continue 3 HIDAC consolidation followed by observation.

2 Acute Promyelocytic Leukemia

Acute promyelocytic leukemia (APML) is a biologically distinct subset of acute myeloid leukemia (AML), which is characterized by t(15;17) translocation resulting in the PML-RARα′ gene, and has unique sensitivity to all-trans-retinoic acid (ATRA) and arsenicals.

2.1 Incidence and Epidemiology in India and Global

About 7–8% of all adult AML cases is comprised of acute promyelocytic leukemia. It is most commonly seen in middle-aged people with a median age of 47 years and is very rare before the age of 20. The incidence is slightly higher in males than females.

2.2 Clinical Presentation in India and Global

Patients with APML frequently present with symptoms arising due to complications of pancytopenia, which includes infections of variable severity, tiredness, weakness and/or hemorrhagic tendencies such as menorrhagia, gingival bleeding, ecchymoses or epistaxis. Patients can rarely present with hyperleucocytosis. More than 50% of patients have pronounced coagulation disorders including a high risk of life-threatening intracerebral hemorrhages.

2.3 Evaluation and Work-up

Suspected APML case should undergo immediate evaluation of

1. Complete blood count, to look for thrombocytopenia, TLC count to categorize APML into high risk or low risk and haemoglobin to look for transfusion requirement.
2. Peripheral blood smear will show abnormal promyelocytes with intense myelo-perioxidase activity.
3. Coagulation profile, PT/INR, APTT, serum fibrinogen level.

Only patients with pancytopenia should undergo bone marrow aspiration and biopsy. In patients with TLC more than 10,000/cumm, peripheral blood should be sent for morphology, cytogenetics, flow cytometry, FISH for t(15,17), RT PCR for PML-RARA transcripts.

Bone marrow is hypercellular, and promyelocytes account for almost all the cells. The typical abnormal promyelocyte can have varying morphology with creased, folded, kidney-shaped nuclei with prominent nucleoli, with pres-

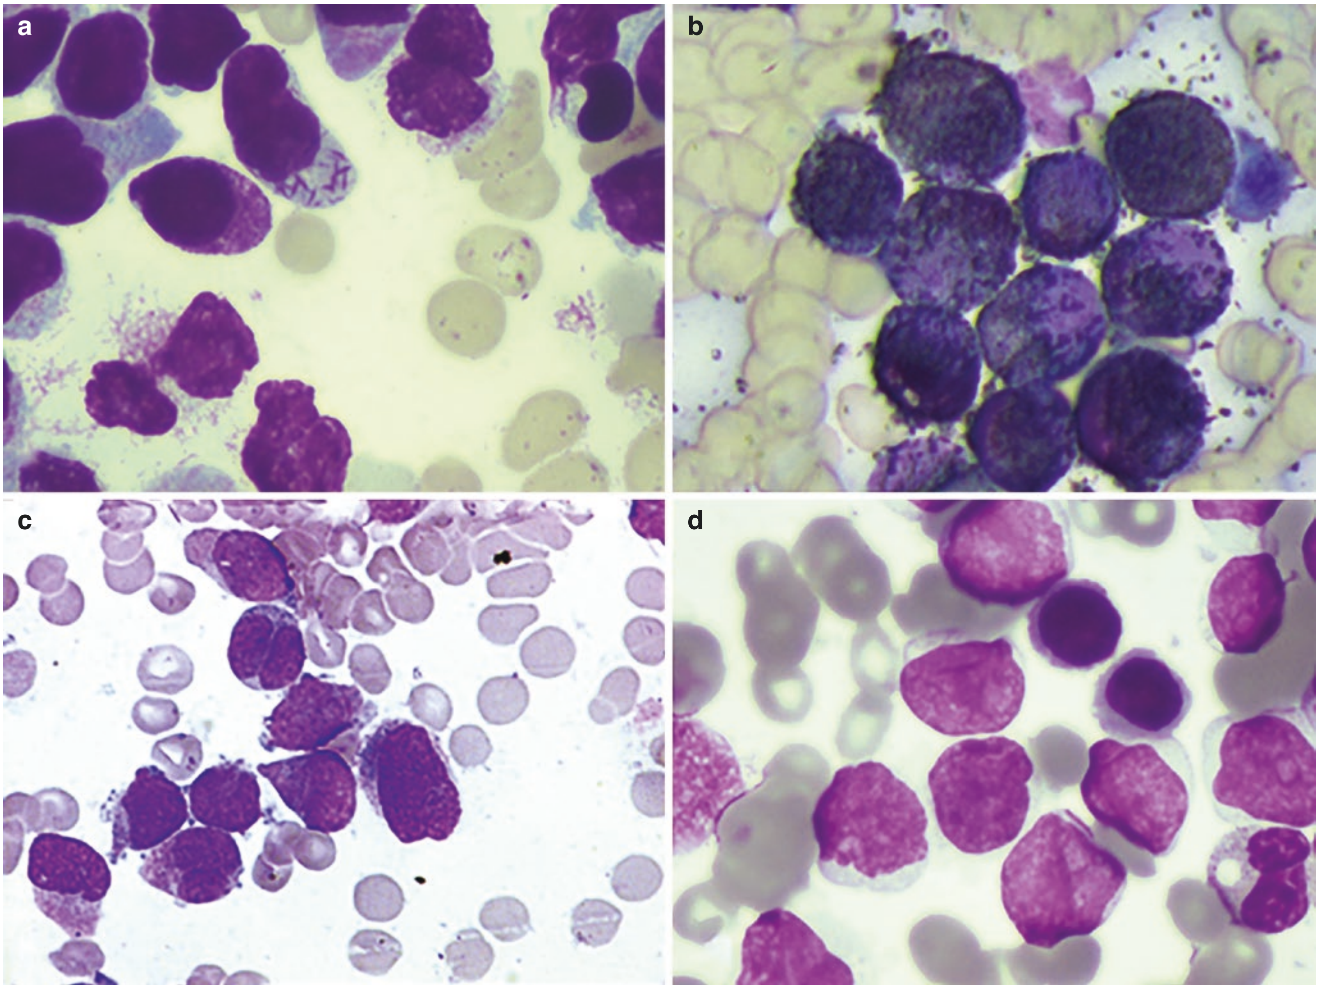

Fig. 1 Various morphology of APML. (**a**) Hypergranular APML with faggot cells. (**b**) Myeloperoxidase staining of the same. (**c**) Abormal promyelocytes with apple core type of nucleus. (**d**) Hypogranular variant of APML

ence of violet granules (which coalesce to form Auer rods) in the cytoplasm. The abnormal promyelocytes can show presence of multiple auer rods called faggot cells which if seen is highly specific for APML. The hypogranular variant (Fig. 1) may not show granules and can appear similar to monoblasts. The hallmark is that all the abnormal cells are positive for cytochemical MPO.

2.3.1 Immunophenotyping

The classic variant express bright cytoplasmic myeloperoxidase (MPO), CD13 and CD33; are usually negative for CD34 and HLA-DR. APML cells also express abnormally low levels of CD15 and weak or variable CD117. The hypogranular variant shows a similar phenotype with a comparably bright MPO expression and frequent co-expression of CD2.

2.3.2 Cytogenetics

The hallmark of APML is a translocation involving *RAR*α′, the retinoic acid receptor alpha locus on chromosome 17. 90% of APML cases contain t(15;17)(q24.1;q21.1). However, several variant translocations involving *RAR*α′ have been identified, including t(11;17) and t(5;17), which are invariably resistant to ATRA.

Fluorescence In Situ Hybridization

FISH for PML/RARA fusion (Fig. 2) is most commonly used and is quicker than conventional cytogenetics. However, both RARA fusion probes and break apart probes have to be used to screen.

Conventional Karyotype

Conventional karyotype can detect rare molecular subtypes of APML and other additional coexistent cytogenetic abnormalities; however, it has a likelihood of missing cryptic translocations.

2.3.3 RT-PCR for PML-RARA RNA

This test helps in confirming the diagnosis of acute promyelocytic leukemia (APML)based on the PML-RARα fusion product of the translocation. It also helps to identify the type

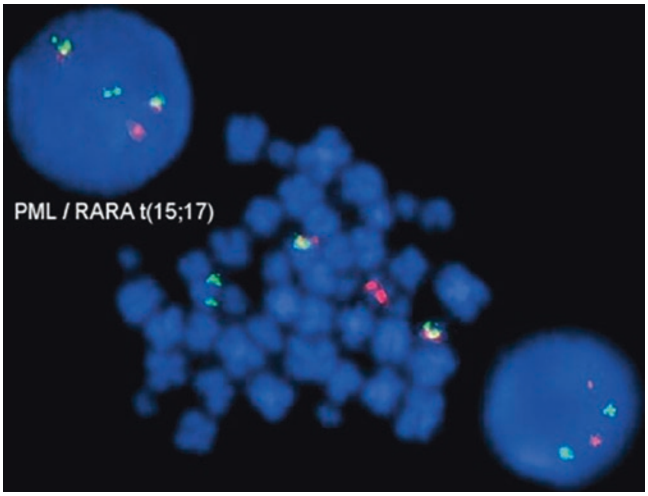

Fig. 2 The interphase cell (round nuclei) and metaphase showing yellow orange fusion signal from green and red probes for PML-RARA fusion

Table 4 Risk-stratification—Sanz score

	Low risk	Intermediate risk	High risk
Leukocytes/μL	<10,000	≤10,000	>10,000
Platelets/μL	>40,000	≤40,000	

Reference: Miguel A. Sanz, Blood (2004)

of transcript for monitoring minimal residual disease. In a small subset of patients, the RT-PCR can pick translocations missed by FISH. The RT-PCR will miss variant translocations if present. NGS can be done to detect additional mutations.

A combination of FISH and RT-PCR gives the best yield to confirm the diagnosis of APML.

2.4 Risk Stratification (Table 4)

2.4.1 Principles of Management

APML is a medical emergency, having a high rate of early mortality, often due to hemorrhage from a characteristic coagulopathy. It is vital that treatment is initiated for all patients without delay y as soon as the diagnosis is suspected based on peripheral smear, before definitive confirmation. On the other hand, arsenic trioxide (ATO) and all-trans retinoic acid (ATRA) can be discontinued if the diagnosis is not confirmed and the treatment modified to that used for other AML types.

Differentiation therapy (ATRA) is the cornerstone treatment in the management of APML and remains as the front line agent in all modern regimens. The concurrent administration of ATRA with cytotoxic chemotherapy results in complete remission in 80–95% of patients. ATO demonstrates synergistic action with ATRA, by inducing differentiation of the malignant myeloid clone by dissociating the PML/RAR-alpha-RXR complex from the target genes.

2.4.2 Medical Management and Monitoring

The treatment comprises of several stages and may span 1–2 years.

- Remission induction
- Consolidation
- Maintenance

Induction-Low- or Intermediate-Risk APL

ATO (0.15 mg/kg) plus ATRA (45 or 25 mg/m^2) as induction is recommended. As compared to ATRA plus anthracyclines, it causes lesser toxicity, fewer deaths during induction therapy, fewer relapses and reduced risk of secondary leukemia. ATO can also be used as monotherapy with encouraging results.

Induction-High-Risk APML

ATO + ATRA + chemotherapy approach: ATO with cytoreductive therapy (Hydroxyurea) should be started on day 1. Once the confirmation by FISH for PML-RARA is available, three doses of anthracyclines like Idarubicin 12 mg/m^2 or Daunorubicin 45 mg/m^2 or Mitoxantrone 12 mg/m^2 is added on alternate days, or Gemtuzumab Ozagamycin 9 mg/m^2 which causes further cytoreduction. Leucopheresis is contra-indicated in APML due to the risk of fatal hemorrhages. ATRA is added once the differentiation is settled at around day8 (ALLG approach).

ATO alone approach is restricted to non-high-risk APML.

ATRA + chemotherapy approach has shown to be effective in several studies with complete remission rates around 90–95%. As ATRA is highly differentiating agent, we avoid using it at the start of therapy.

Prophylactic use of steroids (Inj. Dexamethasone 10 mg BD) can prevent differentiation syndrome with careful monitor for any signs of infection and blood glucose levels.

Monitoring During Induction

1. Blood counts should be monitored daily.
2. Prothrombin time (PT), activated partial thromboplastin time (APTT), fibrinogen level, thrombin time (TT) should be monitored daily until stable, then weekly once.
3. ECG should be monitored twice weekly for QTc prolongation along with.
4. Renal, liver function tests, serum calcium, serum phosphorous and serum magnesium levels.

Blood product transfusion is crucial during induction to prevent bleeding or life-threatening haemorrhages. Platelets should be maintained above 30,000/μL for all patients. If the patient has differentiation or pulmonary or GI bleed, then platelets should be maintained above 50,000/μL. In case of intracranial bleed, maintain platelets above 1 lakh/μL.

To maintain haemoglobin ≥8 g/dL, packed cell should be transfused.

In case of derangement of PT/APTT, fresh frozen plasma should be given at a dose of 15 mL/kg and in case of prolonged thrombin time or low fibrinogen, cryoprecipitate should be given.

Other Issues During Induction

Differentiation Syndrome

Differentiation syndrome is a serious complication with APML that develops after the initiation of differentiating agents. This is mediated by a cytokine release storm which is characterized by fever, rise in counts, disseminated intravascular coagulopathy, hypotension, weight gain due to fluid retention, peripheral or pulmonary oedema hypotension and multi-organ dysfunction which can be fatal, if not promptly recognized. High-dose intravenous corticosteroids are helpful in such cases.

Idiopathic Intracranial Hypertension or Pseudotumor Cerebri

Idiopathic intracranial hypertension or pseudotumor cerebri is a known complication of ATRA, characterized by headaches, papilledema and increased intracranial pressure in the absence of infection or hydrocephalus. The treatment options available for patients with persistent symptoms are corticosteroids, carbonic anhydrase inhibitors (acetazolamide) and analgesics. Also reducing dose of ATRA to 25 mg/m^2 has shown to decrease the adverse effects of ATRA without decreasing its efficacy (Shanghai group).

Response Assessment After Induction

Bone marrow examination for morphology, FISH for t(15,17), RQPCR for PML-RARA for molecular remission is done at the end of induction, prior to starting consolidation to assess for hematological response. If RQPCR for PML-RARA is positive post induction, it is to be repeated post consolidation. According to the new ELN guidelines, achievement of molecular response at the end of consolidation corresponds to complete response without minimal residual disease.

Consolidation

Following confirmation of hematological CR, consolidation is given. Consolidation therapy is administered totargetleukemia cells that survived induction chemotherapy but are not detectable by conventional tests.

Non-High-Risk APML Consolidation

After induction with ATRA plus ATO: 4 courses of ATO (0.15 mg/kg/day, 5 days a week, 4 weeks on and 4 weeks off) + 7 courses of ATRA (45 or 25 mg/m^2) 2 weeks on and 2 weeks off are recommended.

High-Risk APML

After ATO + ATRA + chemotherapy induction: Consolidation is similar to non-high-risk APML protocol.

After ATO-based induction: Consolidation consists of two to three cycles of anthracycline plus ATRA.

Maintenance

For low-intermediate patients, maintenance can be safely omitted. In high-risk cases, maintenance with ATRA, 6-MP and methotrexate for approximately 18 months can be considered.

2.5 Prognosis

APML is a highly curable malignancy. More than 90% of patients with APML obtain a hematologic CR with induction therapy followed by a molecular CR after consolidation therapy. The predominant cause of induction failure (5–10%) is death from hemorrhage or infection, and it is extremely uncommon to have primary drug resistance in APL. The 3-year relapse-free survival of low risk, intermediate risk and high-risk patients are 98%, 89% and 70%, respectively.

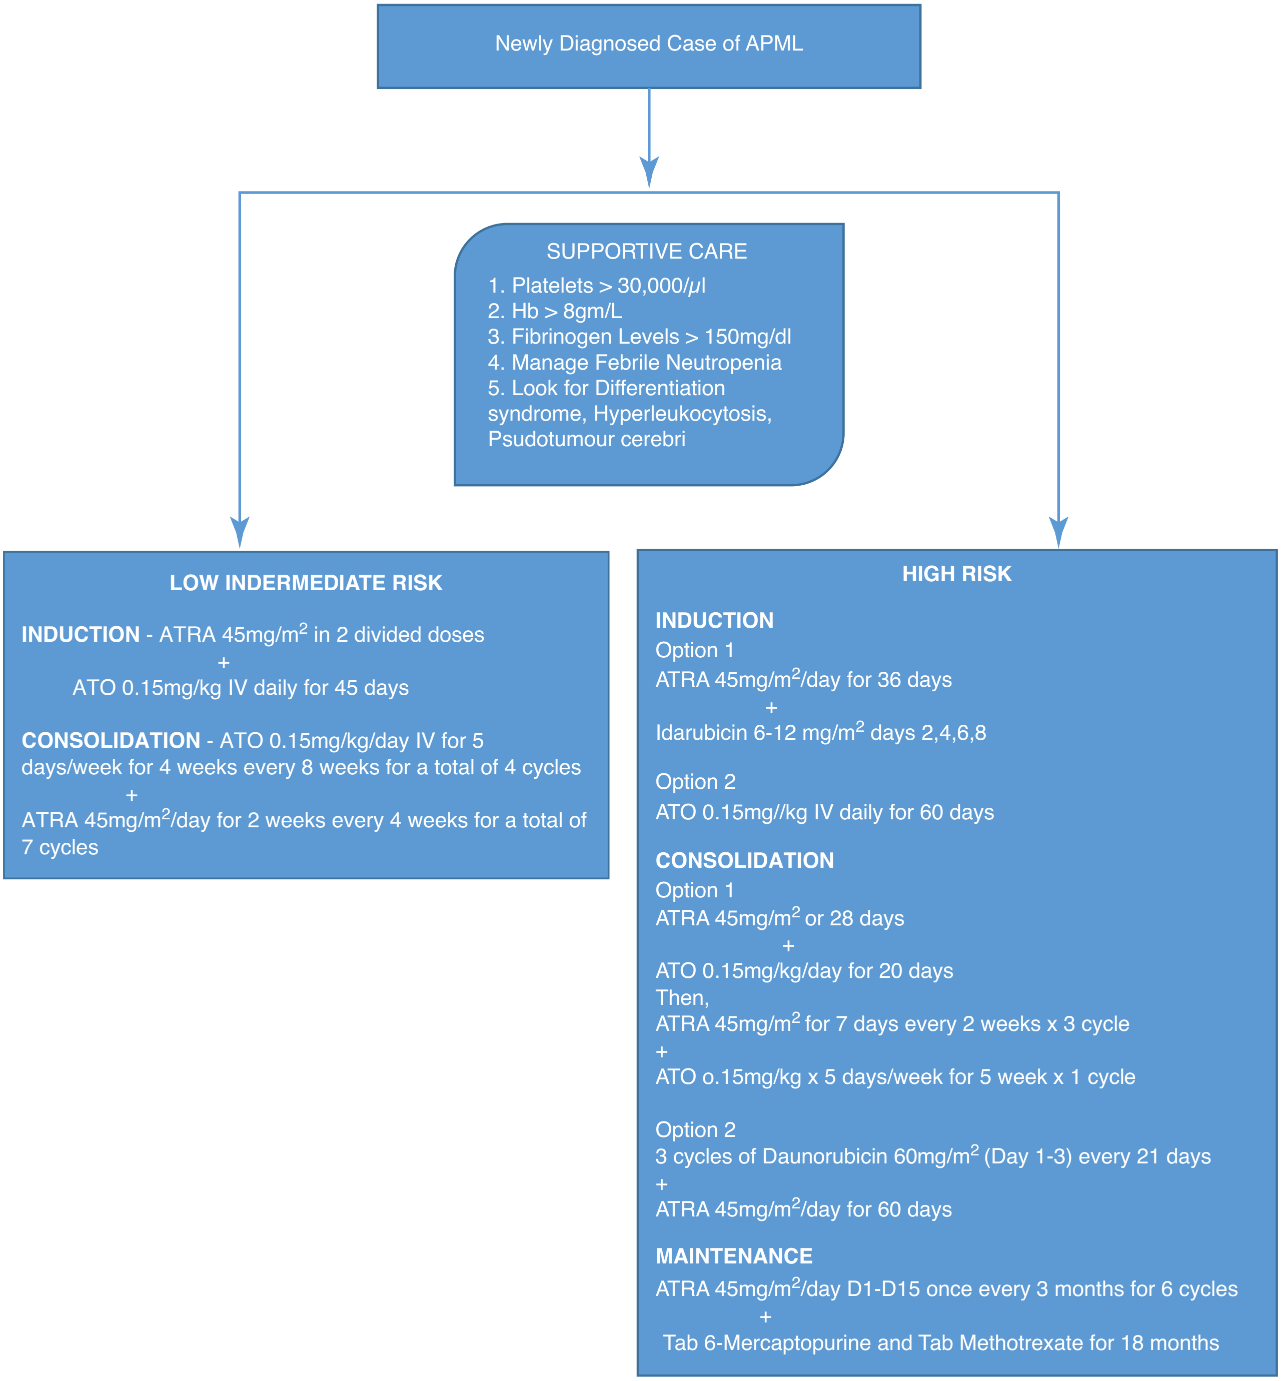
2.6 Management of Resistant/Refractory Disease

Resistant or refractory APML is diagnosed in those patients who do not attain a molecular remission following consolidation chemotherapy. Relapse occurs in 10–15% of patients with APML and in 20–30% of those with high-risk APML. The treatment is generally aimed at achieving remission followed by high-dose chemotherapy and autologous hematopoietic cell transplantation. The choice of therapy depends on the previous therapy used and the timing of relapse. Early relapse (<6 months) cases previously treated with ATRA and ATO are treated with anthracyclines-based regimen. Patients with no prior exposure to ATO and late relapses (>6 months) are treated with ATO-based regimens. The consolidation is with stem cell transplant: autologous in those with molecular remission and allogeneic transplant in those with molecular persistence after consolidation.

2.7 Management for APML (Fig. 3)

2.8 How We Do It at TMC

At our centre, low- to intermediate-risk patients are treated with ATRA plus ATO induction followed by maintenance with ATRA plus ATO. High-risk patients are treated with ATO+ ATRA + Anthracycline followed by ATO/ATRA consolidation like non-high-risk APML protocol. Relapsed patients are managed based on previous treatment, timing of relapse, social support and finances.



Newly Diagnosed Case of APML
SUPPORTIVE CARE
1. Platelets > 30,000/µl
2. Hb > 8gm/L
3. Fibrinogen Levels > 150mg/dl
4. Manage Febrile Neutropenia
5. Look for Differentiation syndrome, Hyperleukocytosis, Psudotumour cerebri
LOW INDERMEDIATE RISK
INDUCTION - ATRA 45mg/m2 in 2 divided doses
+
ATO 0.15mg/kg IV daily for 45 days
CONSOLIDATION - ATO 0.15mg/kg/day IV for 5 days/week for 4 weeks every 8 weeks for a total of 4 cycles
+
ATRA 45mg/m2/day for 2 weeks every 4 weeks for a total of 7 cycles
HIGH RISK
INDUCTION
Option 1
ATRA 45mg/m2/day for 36 days
+
Idarubicin 6-12 mg/m2 days 2,4,6,8
Option 2
ATO 0.15mg//kg IV daily for 60 days
CONSOLIDATION
Option 1
ATRA 45mg/m2 or 28 days

3 Acute Lymphoblastic Leukemia

Acute lymphoblastic leukemia (ALL) encompasses a heterogeneous group of disorders. It is characterized by uncontrolled clonal proliferation of lymphoid cells and their progenitors in the bone marrow, blood and extramedullary sites. Adult ALL constitutes ~20% of all cases. The overall disease prognosis is poor in adults as compared to children. Long-term survival with different regimens is expected to be around 40–50%.

3.1 Incidence and Epidemiology

ALL accounts for 2% of lymphoid malignancies in the USA. No data from India exists regarding incidence/prevalence of the disease.

A retrospective study from CMC Vellore showed median age to be 26 years. About 75% of cases were B cell ALL. CNS disease was seen in 12.5% while testicular involvement was seen in <1%.

3.2 Clinical Presentation

Symptoms of bone marrow failure (weakness, infections and bleeding manifestations), bone pain or joint pain, weight loss, night sweats, hepatomegaly, splenomegaly and lymphadenopathy are the common presentation of the disease. T-ALL may present with a mediastinal mass causing superior vena cava obstruction. CNS involvement will present as cranial nerve palsies (most commonly VI, VIII) or meningismus and is seen in 5–10% cases at baseline.

3.3 Evaluation and Work-Up

1. Complete blood count with peripheral smear: to look for hyperleukocytosis, thrombocytopenia or anemia. Peripheral smear shows myeloperoxidase negative blasts.
2. Renal function test, serum electrolytes including calcium and phosphorus to look for tumour lysis syndrome.
3. Viral markers (HIV serology, anti HCV, HBsAg and HBcIgG).
4. Liver function test and LDH.
5. Bone marrow studies:
   - Morphology, flow cytometry for diagnosis of B or T cell ALL.
   - Cytogenetics: FISH for diagnosis of Philadelphia chromosome or Ph like ALL. And for further risk stratification.
   - Molecular test or NGS: to know the transcript in Ph+ cases or to diagnosis Ph like ALL.
6. CSF cytology and flow cytometry are also needed to know CNS disease status. These investigations will help in diagnosis and risk stratification of the patient.
7. Sperm cryopreservation can be considered in younger males.

As per age and comorbidities, other tests of fitness for chemotherapy are advised. HLA testing of siblings and patient should be done in all high-risk patients.

3.4 Risk Stratification

The following are the adverse prognostic factors:

Age	>35
Baseline WBC	B ALL >30,000 T ALL >1 lakh/μL
Immunophenotype	Pro B ALL, early T cell
Cytogenetics	t(4,11) t (9,22) Hypodiploidy (<44 chromosomes) Complex karyotype (>5 abnormalities)
Therapy response	Time to CR >4 weeks
MRD	>0.01 at 3–6 months after initiation of therapy
Emerging risk factors	
Immunophenotype	CD20
Molecular	BAALC, FUS, ERG, IKZF1, Ph like ALL

3.5 Principles of Management

Patients are divided first as per age. Younger patients (<40 years) are treated with pediatric ALL like protocols and older individuals are treated with adult protocols. The treatment is also based on Philadelphia chromosome status. Patients in whom Philadelphia chromosome is present are treated with the addition of tyrosine kinase inhibitor (TKI).

Treatment for adult ALL can be divided into three phases: Remission induction, consolidation and maintenance. Various protocols are available more or less with same treatment philosophy, e.g. BFM protocol, CALGB protocol, UKALL protocol, etc. All these protocols are not compared head to head but have similar 5-year overall survival of ~40%.

The backbone of induction comprises of steroids, vincristine, L-asparaginase and anthracyclines. CNS prophylaxis in form of intrathecal chemotherapy are part of induction in some protocol while some others have cyclophosphamide and cytarabine. In CD 20 positive cases, Inj Rituximab at 375 mg/m^2 has shown to have 2 years EFS of 65% versus 52% in control arm.

For developing country like ours, we have to balance toxicity of treatment with disease control. In one series it has been shown that in India intensifying treatment regimens does not improve overall survival.

At the end of induction, response assessment with bone marrow flow for MRD, cytogenetics and molecular (RQPCR for BCR ABL in case Ph+ ALL) are done. PETCT is done in case of a mediastinal mass as a presenting feature in T-ALL/LBL.

The consolidation phase is aimed to keep the disease at minimal residual disease level for a prolonged period. 6

Mercaptopurine, methotrexate, cytarabine, cyclophosphamide, etc. are used. For a high-risk patient, consolidation may consist of allogeneic haematopoietic stem cell transplant. Consolidation phase also consists CNS-directed therapy consisting of high-dose methotrexate or cytarabine.

Reintensification phase is a part of consolidation. Which is similar to induction phase but with non-cross resistant chemotherapy agents. Cranial irradiation is given in this phase for CNS prophylaxis.

The maintenance phase is given for 2–3 years with low-dose chemotherapy like 6-mercaptopurine, steroids, methotrexate and vincristine. Ensuring compliance and adequate myelosuppression is a key.

CNS-directed therapy is part of all the protocols either in form of intrathecal methotrexate, intrathecal cytarabine, triple intrathecal chemotherapy, high-dose methotrexate, high-dose cytarabine or cranial irradiation.

In Philadelphia chromosome-positive patients, early addition of tyrosine kinase inhibitor has shown ~90% complete remissions. Dasatinib is preferred over imatinib due to its enhanced efficacy and better CNS penetration.

Day 8 blast count and bone marrow studies at end of induction are done to prognosticate the patient further. It also helps to decide on consolidation strategy.

Allogenic transplant is indicated in all high-risk patients like in those with hyperleukocytosis at baseline, Philadelphia or MLL translocation, ETPALL, CNS-positive disease, minimal residual disease (MRD) positive at end of induction. Though indicated in many, only a very small fraction can undergo a transplant in our setup.

3.6 Supportive Care

Managing toxicity and reducing treatment-related mortality is an important key to treatment in developing countries. Tumor lysis syndrome, hyperleucocytosis, dyselectrolytemia, bacterial infection, fungal infection, viral infection, L-asparaginase induced thrombotic events, methotrexate-related renal injury, etc. are all life-threatening toxicities. Close watch and prompt treatment are needed during these situations. Other common toxicities are raised sugars, constipation, SAIO, peripheral neuropathy, cytopenias, fatigue, anorexia, post-intrathecal chemotherapy headache.

The social and financial support system is as essential as medical treatment.

3.7 Management of Recurrent Disease

Relapse is divided as per duration of remission into very early, early and late. Prognosis of relapsed/refractory patient is guarded. Salvage by multi-agent chemotherapy followed by allogeneic transplant is the only curative option. A significant proportion of patients opt for supportive care only as an option after relapse.

3.8 How We Do It at TMC

We treat patients aged <60 years with modified BFM 90 protocol in a multidisciplinary setting. The treatment of elderly patients is individualized. TKI (Imatinib 600 mg or Dasatinib 100 mg) are added to the chemotherapy regimen in Ph-positive ALL with omission of L-asparaginase. Six weekly doses of Inj Rituximab 375 mg/m^2 is added to BFM 90 protocol in CD20 positive cases. Allogeneic stem cell transplant is considered in high-risk disease.

4 Chronic Myeloid Leukemia

Chronic myeloid leukemia (CML) is a clonal disorder of haematopoietic progenitor cells, caused by an acquired genetic defect in a pluripotent stem cell. The disease is caused due to constitutively active tyrosine kinase B-cell receptor (BCR)-ABL1, resulting from the translocation between chromosome 9 and 22 t(9;22)(q34; q11), which is cytogenetically detected as the Philadelphia (Ph) Chromosome.

4.1 Incidence and Epidemiology of CML in India and Global

The incidence of CML is comparable worldwide with an annual rate of 1.6–2.0 patients per 100,000 persons. Similarly in India, the annual incidence of CML was reported to be 0.8–2.2 per 100,000 population. The median age at diagnosis is 66 years, and has a slight male predominance (2.2:1.3). A recent study from the Mumbai Cancer Registry specifically examined CML and reported an age adjusted rate (AAR; per 100,000) of 0.71 in males and 0.53 in females.

4.2 Clinical Features

- Asymptomatic raised counts
- Easy fatigability
- Anorexia
- Abdominal discomfort
- Early satiety
- Weight loss
- Leukostasis–dyspnoea, priapism
- Rarely bleeding, thrombosis, gouty arthritis

Table 5 WHO definition for stages of CML

CML phase	WHO definition
Chronic phase	Peripheral blood blasts fewer than 10% in the blood and bone marrow
Accelerated phase	• Blasts 10–19% of white blood cells in peripheral and/or nucleated bone marrow cells • Basophils equal to or more than 20% of total nucleated cells • Persistent thrombocytopenia (<100 × 10^9/L) unrelated to therapy or • Persistent thrombocytosis (>1000 × 10^9/L) unresponsive to therapy • Increasing white blood cells and spleen size unresponsive to therapy • Cytogenetic evidence of clonal evolution
Blast crisis	Peripheral blood blasts ≥20% of peripheral blood white blood cells or nucleated bone marrow cells; extramedullary blast proliferation; and large foci or clusters of blasts on bone marrow biopsy

Reference: Daniel A. Arber, Blood (2016)

4.3 Signs

- Pallor
- Splenomegaly
- Sternal tenderness
- Rarely hepatomegaly
- Lymphadenopathy

CML has three phases, which are listed in Table 5.

4.4 Evaluation and Risk Stratification

4.4.1 Blood and Bone Marrow Examination

1. Complete blood count: In the chronic phase of CML, the total leukocyte count usually ranges from 50 × 10^9/L at the time of diagnosis and can extend up to 800 × 10^9/L. Also, a subset of patients may present with mild increase in WBC count and a marked increase in the platelet count.
2. The **peripheral blood smear** shows a full spectrum of myeloid cells from blasts to neutrophils, with blasts comprising less than 10% and usually less than 5% of the WBC differential (Fig. 4). Basophilia is invariably present, and its absence should prompt consideration of other myeloproliferative disorders. Eosinophilia is also commonly present.
3. The **bone marrow** is hypercellular, with a myeloid preponderance (Fig. 5). Blasts percentage depends on the phase of the disease, and basophilia is present. Megakaryocytes are usually increased in number and are characteristically small, hypo- or monolobated, with a tendency to cluster. Erythroid precursors are morphologically unremarkable. Reticulin fibrosis is usually absent or mild and correlates with splenic enlargement. It may become more prominent with disease progression.
4. ***Cytogenetics***: Fluorescent in situ hybridisation (FISH) is a rapid and sensitive test for diagnosis and the standard method to detect philadelphia (Ph) chromosome, which is present in the majority of cells at diagnosis. Although t(9;22)(q34;q11) is common in most patients, approximately 5% have variant translocations that have no impact on prognosis. Additional clonal cytogenetic abnormalities such as duplication of the Ph chromosome, trisomy 8, iso-17q, and trisomy 19 and deletion 7q/7-are present in 5% of cases. Presence of deletion 7q/7-indicates accelerated phase and can be a marker of coexistent myelodysplastic syndrome.

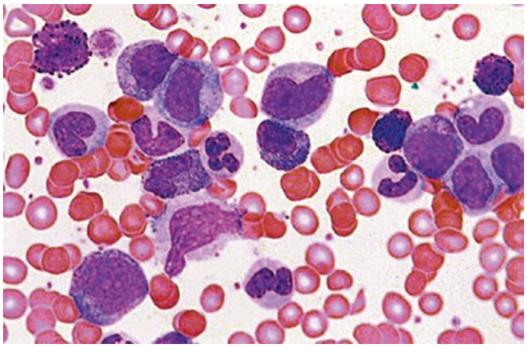

Fig. 4 Peripheral smear of CML

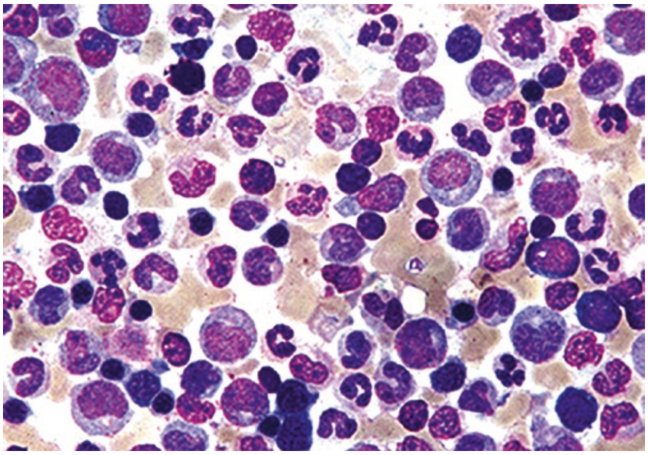

Fig. 5 Bone marrow appearance in CML

Conventional karyotype can be used for diagnosis and to define complete cytogenetic response.

4.4.2 Molecular Tests

Qualitative reverse transcriptase polymerase chain reaction is used to detect and identify the transcript of BCR-ABL (p210 in 90% cases and rarely p190 and p230).

Quantitative PCR is used to follow the molecular response at certain time points.

4.4.3 Prognostic Factors

For treatment-naive CP patients, three risk scores are utilised: Sokal, Euro and EUTOS. The latest addition to prognostic score is ELTS (Eutos long-term survival) score. Other than these scores, presence of fibrosis in the bone marrow biopsy and additional chromosomal abnormalities is considered as high-risk factors for progression and lesser response to TKIs.

4.5 Treatment at TMH

First line treatment options: CML-CP

- Imatinib 400 mg OD
- Dasatinib 100 mg OD
- Nilotinib 300 mg BD

4.6 Practical Management Algorithmwfor CML

The goals of treatment are defined in Table 6.

4.7 Monitoring of CML

1. Complete blood counts: To be monitored once in 2 weeks until achievement of a CHR and then at 1–3 monthly intervals.
2. Cytogenetics: Monitored at 6 months and repeated at 12 months if not in CCYR.
3. Molecular studies: PCR for Bcr Abl should be repeated at 3-monthly intervals, the frequency can be reduced to once in 6 months after MMR is attained (Table 7).
4. Tyrosine kinase domain mutation studies: TKD mutation studies are performed in those who have treatment failure, or present with accelerated/blast phase.

Table 6 Definition of the response to TKIs (any TKI) as first-line treatment

	Optimal	Warning	Failure
Baseline	NA	High risk or CCA/Ph+, major route	NA
3 months	BCR-ABL1 ≤10% and/or Ph+ ≤35%	BCR-ABL1 >10% and/or Ph+ 36–95%	Non-CHR and/or Ph+ >95%
6 months	BCR-ABL1 <1% and/or Ph+ 0	BCR-ABL1 1–10% and/or Ph+ 1–35%	BCR-ABL1 >10% and/or Ph+ >35%
12 months	BCR-ABL1 ≤0.1%	BCR-ABL1 >0.1–1%	BCR-ABL1 >1% and/or Ph+ >0
Then, and at any time	BCR-ABL1 ≤0.1%	CCA/Ph− (−7, or 7q−)	Loss of CHR
			Loss of CCyR
			Confirmed loss of MMR[a]
			Mutations
			CCA/Ph+

[a] PCR >0.1%

Reference: A. Hochhaus, Leukemia (2020)

Table 7 Treatment options based on the BCR-ABL kinase domain mutation status

Mutation	Treatment recommendation
T315I	HSCT/clinical trial
V299L, T315A, F317L/V/I/C	Consider Nilotinib than Dasatinib
Y253H, E255K/V, F359V/C/I	Consider Dasatinib than Nilotinib
Any other mutation	Consider high dose Imatinib or Dasatinib or Nilotinib

Reference: A. Hochhaus, Leukemia (2020)

4.8 Treatment-Free Remission

Discontinuation of TKI can be considered if following requirements are fulfilled:

- Mandatory:
  - In CML-CP only
  - Motivated patient with
  - Access to high quality qPCR with International scale
  - Turnaround time of PCR results <4 weeks
  - Patient's agreement to more frequent monitoring after stopping TKIs (monthly for first 6 months, every 2 months for 6-12 months, every 3 months thereafter
- Minimal:
  - First line therapy or second line if intolerance was the only reason for change on TKI
  - Typical e13a2 or e14a2 BCR-ABL transcripts
  - Duration of TKI therapy for >5 years (>4 years for 2GTKI)
  - Duration of deep MR (MR^4 or better) >2 years
  - No prior treatment failure

Studies that tested the concept of TFR:

1. STIM-1 (Stop Imatinib study)
2. A-STIM
3. Euro-SKI

5 Chronic Lymphocytic Leukemia

CLL is a clinically heterogeneous disease originating from B lymphocytes that may differ in activation, maturation state, or cellular subgroup. Only patients with advanced or symptomatic disease require treatment. Some patients remain indolent with no need for treatment. The 5-year survival for patients with CLL is 55–83%, however it mainly depends on the stage.

5.1 Incidence and Epidemiology in India and Global

CLL is the most common leukaemia in the Western world with an annual incidence of 4.2 patients per 100,000 person population. It comprises 25% of all leukaemia as compared to 1.7–8.8% of all leukaemia in the Indian population. CLL is common in the elderly with a median age of 72 years at diagnosis. The male to female ratio is 2:1. Also, family members of CLL patients have an inherited genetic susceptibility of six- to nine-fold for CLL.

5.2 Clinical Presentation in India and Global

Around 25–50% patients in the west are incidentally diagnosed as compared to 20% of patients in Indian population. Lymphadenopathy is the most common presenting symptom, seen in 87% of patients at the time of diagnosis. Advanced disease with anaemia and thrombocytopenia are present at the time of initial presentation in 20% of cases, and up to 20% of cases present with B symptoms (fever, night sweats and weight loss). Also, 10% of patients may initially present with hepatomegaly and splenomegaly. Autoimmune haemolytic anaemia is present in 10% of patients.

5.3 Evaluation and Work-Up

Clinical history—duration of symptoms, presence or absence of B symptoms, presence of nodal swelling, symptoms of anemia, thrombocytopenia, compressive symptoms due to massive spleen or nodal swelling.

Physical exam with attention to pallor, node-bearing areas, including Waldeyer's ring, and to size of liver and spleen.

Determination of performance status.

5.4 Work-Up for Confirmation of Diagnosis

- Complete blood count and peripheral smear—Diagnosis of CLL requires the presence of $\geq 5 \times 10^9$/L clonal B lymphocytes in the peripheral blood. Peripheral smear demonstrates small, mature-appearing lymphocytes with a narrow border of cytoplasm and a dense nucleus lacking discernible nucleoli and having partially aggregated chromatin. This is accompanied by a small percent of prolymphocytes that are larger cells with more cytoplasm and prominent central nucleoli. It usually shows the presence of smudge cells, which are artefacts from lymphocytes damaged during slide preparation.
- Immunophenotyping—Clonality of the circulating B lymphocytes should be confirmed by flow cytometry. The presence of cell surface markers with dim kappa/lambda, CD19, dim CD20, CD5, variable CD23, and CD200.
- FISH—Cytogenetic abnormalities, in particular a deletion of chromosome 17 [del(17p)], 13[del(13q)] and 11[del(11q)] and trisomy of chromosome 12. These have prognostic and predictive value.
- Molecular analysis to detect *IGHV* mutation status, determination of CD38 and ZAP-70 expression by flow cytometry or immunohistochemistry, TP53 sequencing.
- Bone marrow aspiration and biopsy—Indicated to evaluate for the cause of unexplained cytopenias—autoimmune and myelodysplastic causes.
- Lymph node biopsy—indicated to rule out Richter's transformation.

5.5 Principles of Management

Treatmentoptions for chronic lymphocytic leukemia (CLL) have evolved overthe last several years. The two commonly followed staging systems are the Rai system and Binet system. Generally, patients in the early-stage CLL should not be treated with chemotherapy until they become symptomatic or display evidence of rapid progression of disease. Patients at low and intermediate risk (i.e. Rai stages 0-II) who have no indications for treatment should be observed. Blood cell counts and clinical examinations should be performed every 3–6 months.

5.6 Medical Management and Monitoring

Indications for treatment include the following:

- Presence of B symptoms
- Extreme fatigue (performance score >2)

- Progressive marrow failure (anaemia or thrombocytopenia)
- Autoimmune anemia or thrombocytopenia not responding to glucocorticoids
- Progressive or symptomatic splenomegaly
- Massive or symptomatic lymphadenopathy
- Progressive lymphocytosis, as defined by an increase of >50% in 2 months or a doubling time of less than 6 months

Along with disease-specific measures, complications like tumour lysis syndrome, immune mediated cytopenias, recurrent infections and risk of secondary malignancy should also be addressed. Pneumococcal and influenza vaccines are recommended. Corticosteroids, usually prednisoloneat a dose of 1 mg/kg/day daily initially, followed by gradual dose tapering, may be useful in patients with AIHA. Rituximab, alone or as part of a combination regimen, can be very effective in eliminating the B-cell clone that induces autoimmune disorders, particularly for patients with autoimmune thrombocytopenia.

Therapy recommendations for patients at high risk (i.e. Rai stages III–IV) and progressive cytopenia are based on the following:

- Patient age
- Patient comorbidities
- Presence or absence of del(17p) and IgVH mutation

Treatment options for CLL patients with IgVH mutated status, in the absence of 17p deletion are as follows:

- Patients <65 years, glomerular filtration rate (GFR) >70 mL/min and without significant comorbidities (CIRS Cumulative Illness Rating Scale <6: FCR (fludarabine, cyclophosphamide, rituximab))
- Patients ≥65 years and younger patients with significant comorbidities: Bendamustine + Rituximab (B + R), Ibrutinib, Obinutuzumab plus Chlorambucil.

CLL patients with del(17p) have a poor prognosis and there is no clear standard of care. The treatment options include

- Ibrutinib (ORR 97%, 2 years OS 84%)
- Allogenic stem cell transplant

CLL patients with IGHV unmutated status:

- IGVH unmutated: Ibrutinib is preferred in all patients.

Disease response should be done by clinical examination, blood count monitoring and CT scan or USG Abdomen, CXR after 3 months of therapy.

Minimal residual disease (MRD at <0.01%) at the end of therapy can be used as a prognostic tool to predict time to next therapy and OS.

5.7 Management Algorithm According to Risk Stratification (Fig. 6)

Prognosis

CLL International prognostic score: prognostic factors	Points
Del 17p or TP53 mutation	4
Unmutated IGVH status	2
Serum beta 2 microglobulin >3.5 mg/L	2
Rai stage I–IV	1
Age >65 years	1

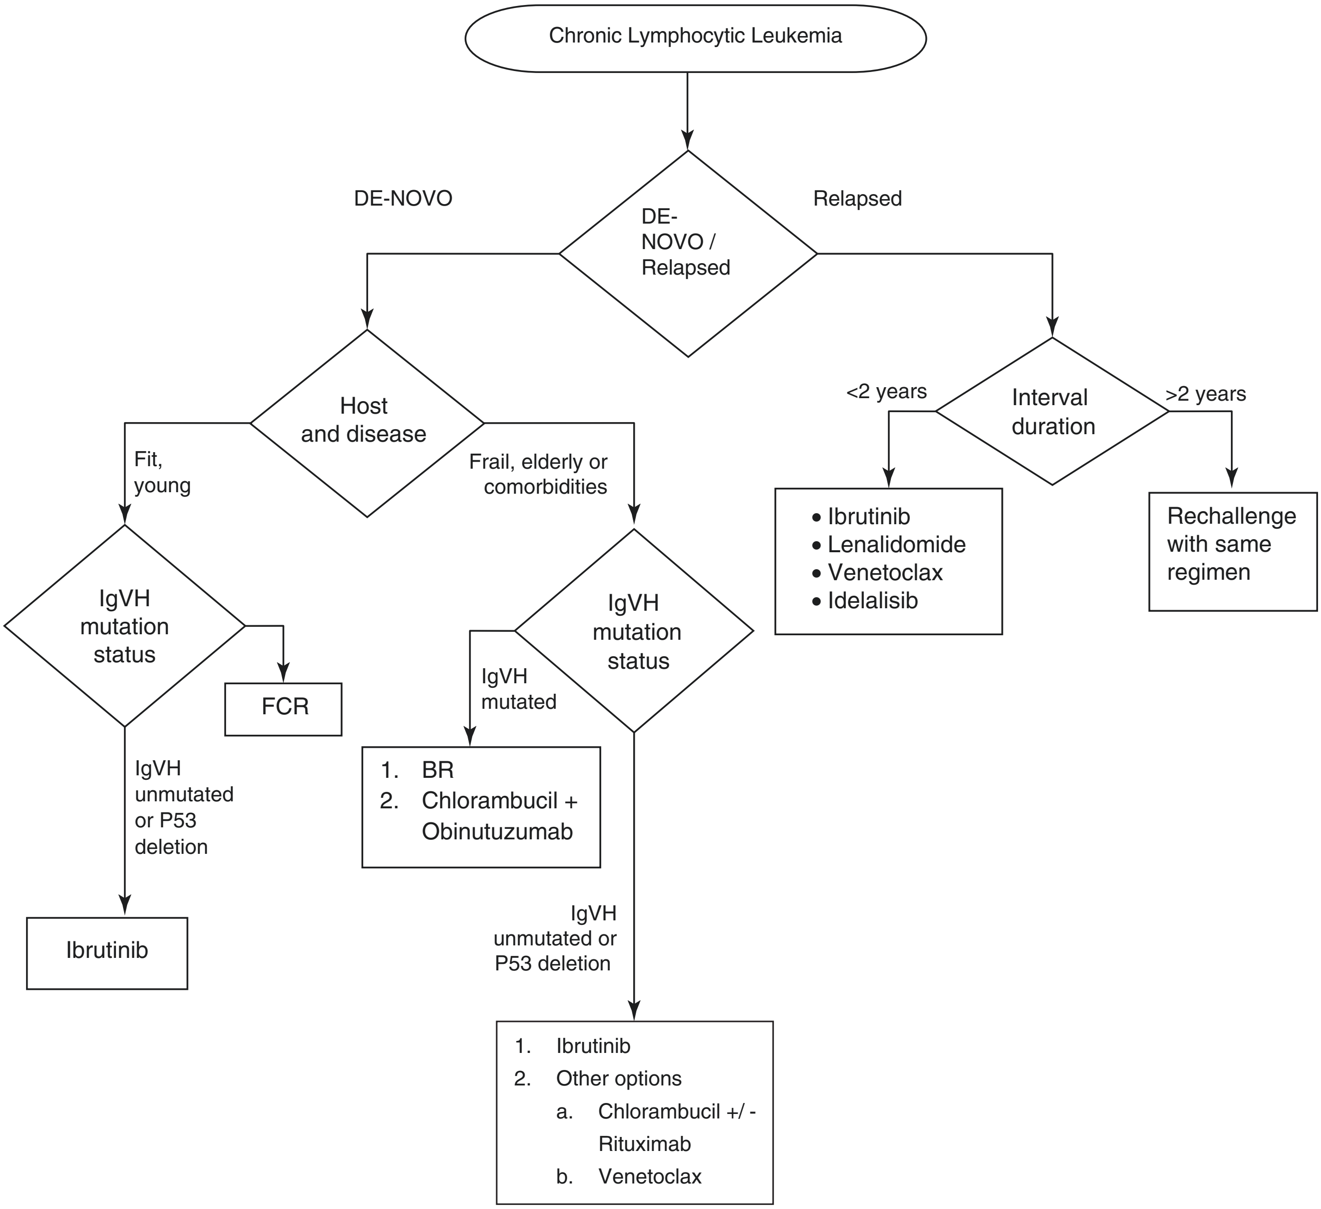
IPI score	Risk	5-year TFS
0–1	Low risk	78%
2–3	Intermediate	54%
4–6	High	32%
7–10	Very high	0%

5.8 Management of Recurrent Disease Including Specific Palliative Measures

Historically, chemoimmunotherapy had been the standard of care for patients with relapsed/refractory CLL. This rapidly changed a few years ago with the introduction of targeted therapies. Treatment for relapsed disease depends on the status of 17p deletion, treatment free interval, age, comorbidities and response and tolerance to previous treatment. Ibrutinib is the preferred drug for patients with relapsed disease if not given upfront. Other drugs that can be used in relapsed/refractory disease include venetoclax plus rituximab, idelalisib, acalabrutinib, chlorambucil with or without rituximab, lenalidomide with or without rituximab and alemtuzumab with or without rituximab. European guidelines recommend allogeneic stem cell transplantation in patients with high-risk *p53* mutation and/or refractory disease to small molecule inhibitor therapy. Richter's transformation to DLBCL is generally managed with chemoimmunotherapy recommended for DLBCL and is associated with poor prognosis. Chimeric antigen receptor therapy (anti CD-19) is under development for relapse/refractory CLL.

5.9 How We Do It at TMC

Patients without 17p deletion are generally treatment with FCR or BR regimen depending on age and comorbidities. Since the generic brand of Ibrutinib is now available in India, at a very low cost compared to the original molecule, patients



Chronic Lymphocytic Leukemia
DE-NOVO
Relapsed
DE-NOVO / Relapsed
Host and disease
Fit, young
Frail, elderly or comorbidities
Interval duration
<2 years
>2 years
• Ibrutinib
• Lenalidomide
• Venetoclax
• Idelalisib
Rechallenge with same regimen
IgVH mutation status

1. Ibrutinib
2. Other options
a. Chlorambucil +/- Rituximab
b. Venetoclax

Fig. 6 Management algorithm for CLL according to risk stratification

with 17p deletion or IGVH unmutated status are treated with Ibrutinib. Treatment of relapsed patients is individualised depending on age, comorbidities, performance status, disease-free interval and logistics.

6 Hairy Cell Leukemia

Hairy cell leukemia (HCL) is a rare variety of mature B cell lymphoproliferative disorder characterized by and named after typical cells seen in peripheral smear. Cell of origin seems to be post germinal memory B cells or possibly splenic marginal zone B cells.

6.1 Incidence and Epidemiology in India and Global

Hairy cell leukemia is uncommon. Its incidence in India is not known. In United States, it accounts for about 1000 cases per year. It is about 4–5 times more common in men than in women.

6.2 Clinical Presentation in India and Globally

Patient presents with pancytopenia or its complications (fever, fatigue andbleeding) and/or splenomegaly (left upper quadrant abdominal pain). Lymphadenopathy is rare and involves the retroperitoneal nodes.

6.3 Evaluation and Work-Up Including Risk Stratification

Complete blood count with peripheral smear (pancytopenia, hairy projections bearing leukemic cells), immunophenotyping (CD19, CD20, CD11c, CD25, CD200, CD103, CD123 and annexin A1), bone marrow studies (aspiration: dry tap and biopsy), viral markers, chest X-ray or CT scan thorax to look for infection. There is specific score to differentiate HCL from HCL-variant and splenic diffuse red pulp small B cell lymphoma. It is very important to differentiate these entities because prognosis and treatment changes with diagnosis. BRAF V600E mutations are seen in almost all patients.

Spleen size, absolute hairy cell count, leucocytosis, beta-2 microglobulin level and IGHV mutation are various factors having prognostic implications.

6.4 Principles of Management (an Integrated Brief Overview of Rx Philosophy)

Treatment is indicated when cytopenias develop or when symptomatic (organomegaly, lymphadenopathy and B symptoms). Asymptomatic patients can be kept under watch and wait strategy.

Purine analogues is the treatment of choice in first line for all HCL patients. Infections should be treated prior to start of purine analogues.

Based on the time to relapse, various strategies are used for attaining remission. Options are to rechallenge with same or other purine analogue, purine analogue with rituximab, BRAF inhibitors, antiCD22 drug conjugate.

6.5 Medical Management and Monitoring

Pentostatin and cladribine in various schedule are drug of choice for first-line treatment. Interferon alpha, low-dose pentostatin or BRAF inhibitors may be used in pregnant female or in case where infection control is difficult. Pentostatin and cladribine are never compared but seems both are equally efficacious. In our setup, generally cladribine is preferred.

Cladribine: 0.1 mg/kg as IV infusion for 7 days
0.14 mg/kg IV over 2 h for 5 days
Pentostatin: 4 mg/m^2 every 2 weeks

Response should be assessed by haematological parameters, physical examination and bone marrow evaluation. CBC should be monitored serially post treatment for count recovery. Bone marrow should be evaluated after about 6 months if cladribine is used or after achievement of clinical response if pentostatin is used. MRD with 8 colour flow cytometry can be helpful to predict long-term remissions.

Some investigators believe in giving consolidation with Rituximab after initial induction with purine analogues.

6.6 Prognosis with Current Rx

Most patients (>90%) can achieve durable long-term remission. Though treatment is not curative, but it can prolong survival to near normal lifespan. Median PFS with purine analogues is 9–11 years.

6.7 Management of Recurrent Disease Including Specific Palliative Measures

Some patients will have stable disease (4%) or PR (20%). Rechallenge with other purine analogue is an option for them. Those who do not respond to two lines of purine analogues alternative treatment options like anti CD22 (moxetumomab pasudotox-tdfk), BRAF inhibitors (vemurofenib), bendamustine plus rituximab, single-agent rituximab, interferon alpha, splenectomy or other investigational therapies.

Treatment for relapse patient depends on time to relapse. For patients who relapse after more than 5 years, the same purine analogue should be rechallenged or another nucleoside analogue can be used. For those who relapsed between 2 and 5 years, purine analogue plus rituximab should be used. For those who relapsed before 2 years one should confirm the diagnosis and if confirmed than one should use alternative options like anti CD22 (moxetumomab pasudotox-tdfk), BRAF inhibitors (vemurafenib), bendamustine plus rituximab, single-agent rituximab, interferon alpha, splenectomy or other investigational therapies.

Splenectomy is used sometimes in very symptomatic patient or in pregnant patient for palliative measure.

6.8 How We Do It at TMC

We manage HCL patients with single-agent cladarabine 0.1 mg/kg IV infusion for 7 days along with supportive care including antibacterials, antifungal in first line. We observe patients after induction and do bone marrow for response evaluation at about 6 months. Relapsed and resistant patients are treated on a case-by-case basis based mainly on time to relapse.

1 Introduction

The term “lymphomas” comprises of biologically and clinically heterogeneous group of neoplasms that are derived from the cells of lymphoid lineage. Conventionally, they have been divided into non-Hodgkin lymphoma (NHL) and Hodgkin lymphoma (HL). There has been significant progress in understanding of the biology and therapeutics of lymphomas over the past few decades. The molecular characterization and various genetic abnormalities associated with the development of lymphomas has led to the notion of lymphomas being clonal expansion of B and T lymphocytes. Hodgkin lymphoma is a B-cell malignancy characterized by the presence of large atypical cells—the Hodgkin–Reed–Sternberg (HRS) cells scattered in a complex inflammatory stroma [1]. Biology, treatment and outcomes vary based on the subtype of Hodgkin and non-Hodgkin lymphomas [2].

2 Incidence and Epidemiology

Non-Hodgkin lymphoma (NHL) is a common hematological malignancy. They comprise a heterogeneous group of disorders and account up to 3–5% of all malignancies. According to Globocan (2018), the estimated incidence of NHL is 6.6/100,000 (509,590 new cases), with a mortality rate of 2.6% of all cancer-related deaths (248,724 deaths) worldwide [3]. The estimated incidence of HL is 1.03/100,000 with a mortality rate of 0.3% of all cancer-related deaths worldwide. The age-adjusted incidence rates for NHL in men and women in India are 2.9/100,000 and 1.5/100,000, respectively [4]. The incidence is significantly lower than Western countries. The variation in incidence between urban and rural cancer registries within India suggest potential role of urbanization and lifestyle changes. There is a variability in the frequency of various subtypes of NHL in India as compared to Western countries. Diffuse large B-cell lymphoma is the commonest subtype followed by follicular lymphoma, small lymphocytic lymphoma/chronic lymphocytic leukemia, mantle cell lymphoma and marginal zone lymphoma. The prevalence of T-cell lymphoma is higher than the western countries but lower than the other Asian countries. Among the T-cell lymphomas, T-cell lymphoblastic lymphoma, anaplastic large cell lymphoma and other nodal peripheral T-cell lymphomas account for 6%, 4.3% and 2.9% of all cases, respectively. The median age of diagnosis varies based on the subtype of lymphoma [5, 6].

https://doi.org/10.1007/978-981-99-3378-5_20

The age of onset of HL reveals a bimodal distribution with a first peak in the third decade and a second peak after the age of 50. It affects men more commonly age compared to women [7].

Several risk factors for development of non-Hodgkin lymphoma have been evaluated. These include immune deficiency, autoimmune disorders, infections, environmental factors, genetic predisposition and obesity [8]. Genome-wide association studies have identified loci that are associated with increased for follicular lymphoma, marginal zone lymphoma and DLBCL. Autoimmune diseases including rheumatoid arthritis, Sjogren syndrome and systemic lupus erythematosus contribute to the development of NHL through underlying altered immune dysregulation and immunosuppressive therapy. Patients with primary or secondary immunodeficiency (organ transplantation and HIV/AIDS are at an increased risk of developing NHL. Infections, like *Helicobacter pylori* (gastric mucosa-associated lymphoid tissue), Epstein–Barr virus (Burkitt lymphoma and NK–T-cell lymphoma) and Hepatitis C virus (splenic marginal zone lymphoma) have shown to be causative for certain specific subtype [9–11].

The etiology of HL is not well understood. Epstein–Barr virus (EBV) and immunodeficiency have shown to increase the risk [12, 13].

3 Clinical Features and Staging of Lymphomas

The most common presentation of patients with NHL is painless lymphadenopathy, with or without constitutional symptoms such as fever, nights' sweats, weight loss and fatigue. In HL patients may present with relatively long-standing duration of painless lymphadenopathy. The most common sites of disease presentation—cervical, mediastinal and/or abdominal nodal enlargement. Symptoms vary based on the site of involvement. Superior vena cava obstruction, cough, shortness of breath can occur due to mediastinal lymphadenopathy. Abdominal lymphadenopathy can present as abdominal pain or obstructive symptoms. Similarly, extranodal site of involvement can present as mass or organ specific symptoms. Pruritus with or without skin lesions indicate the possibility of HL.

The Ann Arbor staging system was first developed for staging of HL and later was used for NHL too [14]. The Ann Arbor staging system divides patients into four stages based on nodal site location, number of nodal areas, presence and extent of extranodal sites, liver and bone marrow involvement (Table 1). The staging system has evolved over the years and now with the use of PET-CT, Lugano staging criteria are used for both HL and NHL which are FDG (fluorodeoxyglucose) avid (Table 2).

Table 1 Ann Arbor classification and the Cotswold modifications

Stage	Features
I	Involvement of a single lymph node region or lymphoid structure (e.g., spleen, thymus, Waldeyer's ring)
II	Involvement of two or more lymph node regions on the same side of the diaphragm
III	Involvement of lymph regions or structures on both sides of the diaphragm
IV	Involvement of extranodal site(s) beyond that designated E
For all stages	
A	No symptoms
B	Fever (>38 °C), drenching sweats, weight loss (10% body weight over 6 months)
For stages I to III	
E	Involvement of a single, extranodal site contiguous or proximal to known nodal site
Cotswold modifications	Massive mediastinal disease has been defined by the Cotswold meeting as a thoracic ratio of maximum transverse mass diameter greater than or equal to 33% of the internal transverse thoracic diameter measured at the T5/6 intervertebral disc level on chest radiography. The number of anatomic regions involved should be indicated by a subscript (e.g., II3) Stage III may be subdivided into: III1, with or without plenic, hilar, celiac or portal nodes; III2, with para-aortic, iliac, mesenteric nodes Staging should be identified as clinical stage (CS) or pathologic stage (PS) A new category of response to therapy, unconfirmed/uncertain complete remission (CR) can be introduced because of the persistent radiologic abnormalities of uncertain significance

Table 2 Revised staging system for primary nodal lymphomas

Stage	Involvement	Extranodal (E) status
Limited		
I	One node or a group of adjacent nodes	Single extranodal lesions without nodal involvement
II	Two or more nodal groups on the same side of the diaphragm	Stage I or II by nodal extent with limited contiguous extranodal involvement
II bulky[a]	II as above with "bulky" disease	Not applicable
Advanced		
III	Nodes on both sides of the diaphragm; nodes above the diaphragm with spleen involvement	Not applicable
IV	Additional noncontiguous extralymphatic involvement	Not applicable

NOTE. Extent of disease is determined by positron emission tomography-computed tomography for avid lymphomas and computed tomography for nonavid histologies. Tonsils, Waldeyer's ring, and spleen are considered nodal tissue

[a] Whether stage II bulky disease is treated as limited or advanced disease may be determined by histology and a number of prognostic factors

4 Evaluation and Work-Up of Lymphomas

4.1 Lymphoma Diagnosis: Lab Approach

4.1.1 Morphological/Histopathological Approach to Lymphoma Diagnosis

Lymphoma diagnosis is based on an adequate and representative biopsy sample to be reviewed by a hematopathologist. It is preferable to have an excisional biopsy of the largest palpable lymph node or of the lesion in the extranodal site. Sometimes incisional or core biopsy is the only feasible option. Diagnosis based only on morphology of a fine-needle aspiration cytology or an effusion should be avoided unless until it is supplemented with ancillary techniques like flow cytometry or molecular diagnostics. Morphological mimics of various subtypes of lymphoma are many, and differential diagnosis varies for each specific morphological subtype.

Optimal fixation and processing of tissue is mandatory for morphological as well as immunophenotypic interpretation. A good quality H&E section is a key to lymphoma diagnosis. It is important to have a low power lens in the microscope, preferably 1× (expensive) or else a 2× lens.

4.1.2 Immunophenotyping

IHC is routinely available in most surgical pathology laboratories and help in work up of hematolymphoid neoplasms. There are more than 250 CD markers available today and approximately 40–45 being routinely used in IHC labs for diagnosis of HLN (Table 3). It is important to understand reactions of these markers with respect to normal cells in the lymphoid and other organs. An example is of Bcl-2 reaction in a normal lymph node. Bcl-2 is commonly used in the differential diagnosis of follicular lymphoma from follicular hyperplasia. In a normal node Bcl-2 is expressed by mantle cells, marginal zone cells, interfollicular T cells and in follicular T helper cells (CD4+) present within the germinal centers. Similarly, Pax5 is a B-cell transcription factor with strongest expression in mantle zone cells, weak to moderate in germinal center B cells, weak in RS cells (in CHL) and negative in plasma cells and T cells. CD138 is a marker for plasma cells and is also expressed in epithelial cells. CD10 is a marker used in hematolymphoid neoplasms where it is expressed in precursor B-cell ALL, DLBCL, FL, BL, AITL and also in benign lymphoid cells like hematogones and also in neutrophils and stromal cells. CD10 expression in neutrophils is used as an internal control in FCI.

4.1.3 Cytogenetics

Cytogenetics has an equally important role in diagnosis and prognostication of various lymphomas. Interphase fluorescent in-situ hybridization (FISH) is performed in lymphomas as it is difficult to get adequate mitoses in lymphoma cells. FISH analysis can be performed on peripheral blood, bone marrow aspirate, fluids or cytology smears, lymph node paraffin sections, etc. The panel for FISH is mainly dependent on the final tissue diagnosis. Specific chromosome abnormalities are strongly associated with particular subtypes of lymphomas, e.g., t(8;14) or variants in Burkitt lymphoma and t(11;14) in Mantle cell lymphoma, etc.

Table 3 Immunohistochemistry for diagnosis of lymphomas

Essential markers for a hematopathology laboratory
LCA, CD20, CD3, CD5, CD23, CyclinD1, Mib1, CD10, bcl6, bcl2, CD43, CD15, CD30, Alk1, Pax5, Tdt, CD34, CD138, MPO, Mum1, CKIT, EBVLMP1/EBER (ISH)
Comprehensive panel of antibodies as a lymphoma panel
B-cell lymphoma panels: CD20, CD79a, CD19, CD23, CD10, MYC, CD5, BCL2, BCL6, Ki67, IRF4/Mum1, CD21, CD23, CD35, Cyclin D1, Pax5, Tdt, CD138, kappa and lambda light chains, CD43, p21, Annexin A1, CD123
Hodgkin lymphoma panel: LCA, CD3, CD20, CD15, CD30, Pax5, ALK1, IRF4/Mum1, EBV-LMP1, EBE-EBER (ISH), Oct2, Bob1, EMA, CD57
T/NK cell lymphoma panel: CD2, CD3, CD4, CD5, CD7, CD8, CD56, Ki67, CD23, CD10, CD25, CD30, Alk1, Tdt, CD56, CD57, Perforin, Granzyme, TIA-1, PD1, CD123
Miscellaneous: C-kit, MPO, CD33, HLADR, CD1a, CD163, CD61/CD41, CD235, CD71, etc.
Other markers: CK, EMA, S-100, HMB45, Melan A, Desmin, Mic2, FLI1, MyoD1, Myogenin, Synaptophysin, Chromogranin, ER, PR, Cerb b2
Different lymphoma subtypes and panels
DLBCL: CD10, bcl6, Mum1, Mib1, bcl2, MYC
Plasma cell neoplasms: CD79a, CD38, CD138, kappa/lambda light chains, CD56, EMA, Mum1, cyclinD1, CD19, C-kit
Small cell lymphomas: CD5, CD23, CyclinD1, bcl-6, CD10, CD43, bcl2
Burkitt lymphoma: bcl2, MiB1, CD10
Lymphoblastic lymphoma: CD3, CD99, TdT, Pax5, CD79a, CD10, CD4, CD8 (for B-LL, CD79a and CD19 are better markers as the blasts might be negative for LCA and CD20)
Granulocytic sarcoma: CD43, MPO, cKit, CD34
ALCL: CD30, ALK-1, EMA, CD3, CD4, CD8, CD20
PTCL/AITL: CD3, CD2, CD5, CD7, CD56, CD30, ALK1, CD23, CD10, CD4, CD8, PD1, Tdt
Suspected NK cell lymphoma: CD3, CD56, CD57, EBER (Others: CD8, TIA-1, granzyme B)
Histiocytic differentiation: PGM1 (CD68), CD163, CD1a
Dendritic cell: CD21, CD23, CD35, S-100
Classical HL: LCA, CD3, CD20, Pax5, CD15, CD30, Alk1, EBER ISH, EBV LMP1
NLPHL: CD20, CD3, CD56, Oct2, Bob1, CD23, CD30, EBER, EBVLPM1
Cutaneous lymphomas: CD3, CD20, CD4, CD8, CD5, CD7, CD10, CD30, BCL2
EBV-related lymphomas: EBER by in-situ hybridization

4.1.4 Molecular Tests

T and B lymphoid cells are involved in immune function for the recognition of foreign antigens by the specificity of their surface T-cell receptor (TCR) and immunoglobulin, produced by gene rearrangement. Each T and B lymphocyte carries a unique arrangement of TCR or immunoglobulin genes, which helps in identification of clonality of mature T- and B-cell proliferations. IGH and TCR gene rearrangement by polymerase chain reaction (PCR) can be performed on any sample, i.e., peripheral blood, bone marrow aspirate or paraffin-embedded tissues (lymph node or bone marrow biopsy). Molecular studies are important for diagnosis, as well as for detection of minimal residual disease. While the use of PCR for specific translocations such as t(14:18) and for detection of T-cell and B-cell clonality based on TCR and Ig heavy and light chain gene rearrangement studies is an important diagnostic test, false positives and negatives are not uncommon; therefore, PCR results should not form the sole basis for diagnosis. Diagnosis of hematolymphoid neoplasms is based on a multidisciplinary approach.

The **staging work-up** includes a detailed history taking and physical examination; laboratory studies to assess the organ function, serum lactate dehydrogenase; and imaging studies.

For HL FDG-avid NHL subtypes, PET-CT improves the accuracy of staging compared with CT and tends to upstage in 10–20% of patients. In majority of cases, the upstaging does not alter the management and may not have impact on the overall survival. It helps in improving staging accuracy ensures that fewer patients are undertreated or overtreated [15, 16].

Bone marrow biopsy (BMB) is an important component of staging in NHL. Patients who demonstrate bone marrow involvement on PET-CT need not undergo a bone marrow examination unless the discordant histology is being suspected. The negative predictive value of PET-CT in NHL is not as good as HL. In patients with HL, BMB is not required if a staging PET-CT is done [17]. In diffuse large B-cell lymphoma (DLBCL), PET-CT is more sensitive than BMB but has been reported to miss low-volume diffuse involvement of 10–20% of the marrow [18]. In all other lymphoma subtypes a 2.5-cm long unilateral BMB and aspiration is recommended, subjected for immunohistochemistry and for flow cytometry.

Several systems for predicting prognosis or prognostic indices have been developed for different lymphoma subtypes. The value of these indices is dependent on the treatment being offered. n. International prognostic index for aggressive B-cell lymphoma has been modified over the years to delineate its role based on the age, stage and use of rituximab [19]. Modification of the IPI for DLBCL seems to improve its predictive value. Other systems exist, sometimes with several iterations, for follicular lymphoma, mantle cell lymphoma, peripheral T-cell lymphoma and NK–T-cell lymphoma [20–23].

5 Principles of Management of Lymphomas

Lymphomas are essentially curable malignancies. Apart from asymptomatic low grade/indolent lymphomas which may be managed by a wait and watch policy, majority of the lymphomas merit treatment with chemotherapy. Systemic therapy remains the primary modality of treatment for majority of HL and NHL. The selection of drugs, regimen and duration is decided based on the subtype and stage of the disease.

The role of surgery is limited to the initial diagnostic workup (excisional and incisional biopsy) or for management of oncological emergencies like acute abdomen and cord compression. Critically important in the diagnosis and staging process but recently has had limited importance. Radiotherapy is used in combination with chemotherapy as consolidation or to address the residual disease or as part of combined modality therapy. In low-grade lymphomas with limited stage disease radiotherapy can be the only modality of treatment.

Supportive care has a pivotal role in the management of lymphomas. It is required during the entire continuum of treatment. High-tumor burden, tumor lysis syndrome, superior vana cava syndrome, massive pleural effusion, pericardial effusion, acute abdomen, cord compression and renal dysfunction due to obstructive uropathy will need urgent attention to enable the delivery of definitive treatment. During therapy, management of nausea and vomiting, mucositis, febrile neutropenia and other treatment-related side effects are crucial to reduce the morbidity, treatment compliance and mortality.

6 Management of Non-Hodgkin Lymphomas

6.1 Precursor B- and T-Cell Lymphomas

Lymphoblastic lymphoma (LBL) can be of pre-B-cell or pre-T-cell origin and is evaluated and treated on similar lines as acute lymphoblastic leukemia (ALL). The clinical presentation includes mediastinal mass in T-LBL, whereas skin, bone and nodal involvement are common in B-LBL. T-LBL presents at younger age as compared to B-LBL. LBL tends to involve central nervous system like ALL, and therefore, a baseline cerebrospinal fluid (CSF) examination is mandatory. The treatment is based on pediatric inspired ALL regimen in patients who are fit. Use of prophylaxis for CNS is mandatory. Mediastinal radiation is used in patient treated with adult protocols. Like ALL, maintenance therapy is essential component of treatment [24].

6.2 Mature B-Cell Lymphomas

6.2.1 Diffuse Large B-Cell Lymphoma (DLBCL)

DLBCL is the most common subtype of non-Hodgkin lymphoma. Chemoimmunotherapy with R CHOP (rituximab plus Cyclophosphamide doxorubicin vincristine and prednisolone) remains the cornerstone for management of DLBCL and led to a significant improvement of outcomes [25].

Based on the cell of origin, DLBCL is divided into two subtypes—germinal center type (GCB) and activated B-cell type (ABC). The GCB type have a better prognosis than ABC type. Though rituximab has led to significant improvement in outcomes of both the subtypes, it does not overcome the negative prognostic effect of the activated subtype [26].

Patients with early stage DLBCL have an excellent outcome with the long-term survival close to 80–90%. Abbreviated chemotherapy with radiotherapy can be employed, but chemoimmunotherapy alone can cure most patients [27]. In the rituximab era, the role of radiotherapy in patients with negative PET-CT after the chemoimmunotherapy is questionable.

Lymphomas with mutations/gene rearrangements involving both MYC and either Bcl-2 or Bcl-6 genes have been referred to as double-hit lymphomas. They exhibit features intermediate between DLBCL and Burkitt lymphoma. DLBCLs with MYC and Bcl-2 mutations are of germinal center B-cell origin, and those with MYC and Bcl-6 are often of activated B-cell origin [28]. Double-hit lymphomas respond poorly to the standard R CHOP, have a lower incidence of complete remission and increased likelihood of primary progression on therapy. The risk of CNS relapse is also high. Many attempts to improve the outcome of patients with the double-hit subtype type of DLBCL have been studied. Infusional EPOCH-R regimen with CNS prophylaxis (commonly with intrathecal methotrexate) is one such development but with limited success. Lymphomas that overexpress the proteins Bcl-2 and MYC but do not have translocations in the respective genes have been referred to as double expressors: usually of activated B-cell origin and have a poor outcome. However, the outcome is intermediate between double-hit DLBCLs and DLBCLs that are neither double-hit nor double expressors.

The risk of CNS relapse in patients with advanced DLBCL is about 5% and reaches to nearly 15–20% for patients with high IPI score. Chemoimmunotherapy alone does not reduce the risk of CNS relapse. Specific extranodal sites such as testes, orbit, kidneys, adrenal, breast, paranasal sinuses, paravertebral masses and marrow are more frequently associated with CNS involvement. Patients with high IPI score, high-levels of LDH and involvement of more than one extranodal site are at much higher risk of CNS relapse. Hence, in these patients, incorporation of CNS prophylaxis either in the form of intrathecal methotrexate or high-dose methotrexate is beneficial.

DLBCL subtypes arising in extranodal sites can have unique clinical features. Primary mediastinal B-cell lymphoma is seen more often in young women and it has tendency to spread to other extranodal sites [29]. With CHOP-R alone the outcomes are inferior when compared to intensive alkylator-based protocols like MACOP-B or HperCVAD. However, toxicities preclude the usage of these regimens commonly. In one study of EPOCH-R without radiotherapy, event-free survival was reported to be 93%. A negative PET-CT at the end of chemotherapy facilitates the omission of mediastinal radiation and thus spare the patients of its long-term toxicities [30].

In case RCHOP is used, a combination with radiotherapy is mostly required.

Primary CNS lymphoma can be cured by chemotherapy regimens that include high-dose methotrexate and/or high-dose cytarabine during the induction. Consolidation with high-dose chemotherapy and autologous stem cell transplant is a viable option in suitable patients. Given its long-term side effects, especially neurocognitive and behavioral, cranial irradiation, is not primarily used for consolidation unless residual disease persists post induction [31].

6.2.2 Burkitt Lymphoma

Burkitt lymphoma is the most rapidly proliferating human malignancy (doubling time of 24–48 h), and because the disease can progress so rapidly and has a tendency to disseminate to the CNS, a timely diagnosis and prompt institution of effective therapy are important. Staging must be completed rapidly in order to avoid delay of therapy, which must start within 48 h after diagnosis.

CNS directed prophylactic therapy must be included and is the backbone in any treatment protocol employed for Burkitt lymphoma. Very intensive, short-course, multiagent, noncross-resistant alkylator-based, chemotherapy regimens can cure most of the patients. There is no role for maintenance therapy or bone marrow transplantation. Studies report an 80–90% survival rate among adults with Burkitt lymphoma who are given popular regimens such as R CODOX-M-IVAC (the combination of cyclophosphamide, vincristine, doxorubicin and methotrexate with etoposide, ifosfamide and cytarabine), hyper-CVAD-RMA (the combination of cyclophosphamide, vincristine, doxorubicin, dexamethasone, methotrexate and cytarabine) and other similar regimens [32–35]. However, toxicities both short-term and long-term failures to complete the therapy and treatment-related mortality are major hurdles for delivering these intense regimens. The addition of rituximab to treatment regimens appears to improve the outcome [36]. The survival rate among adults with Burkitt lymphoma who are given an intermediate intensity infusional chemotherapy regimen EPOCH-R is more than 90%, and this regimen appears to be more tolerable in adults [37]. The German Multicenter Study Group for Adult Acute Lymphoblastic Leukemia (GMALL) used a modified regimen that was better tolerated in older patients with a 5-year progression-free survival reaching nearly 60–65% in patients with Burkitt lymphoma older than 55 years [36]. The regimen to be employed is a clinical decision based on the patients' age and general condition. The role of prephase, supportive care including prophylaxis and management of tumor lysis syndrome is the cornerstone for the successful management of Burkitt's lymphoma.

6.2.3 Mantle Cell Lymphoma

Mantle cell lymphoma was recognized as a distinct entity in the 1990s, and with chemoimmunotherapy, the survival of patients has considerably improved. A subset of patients with mantle-cell lymphoma who present with blood and bone marrow involvement, splenomegaly can have an indolent course akin to low grade lymphomas [38]. Most patients with mantle-cell lymphoma require therapy sooner or later after diagnosis. The outcomes of mantle cell lymphoma with R CHOP alone are modest. High-dose cytarabine-based regimens have shown remarkable activity in these patients [39]. Autologous hematopoietic stem-cell transplantation during the first remission is often incorporated as part of the initial treatment [40]. Maintenance rituximab is recommended post auto transplant and in patients with complete remission post induction. Bendamustine and rituximab have shown improvement in progression-free survival as compared to RCHOP in patients deemed unfit for intensive treatment and ineligible for autograft [41]. The advent of small molecule inhibitors like ibrutinib, acalabrutinib and venetoclax in the relapsed refractory setting has led to more patients receiving these treatments.

6.2.4 Marginal Zone Lymphomas

Marginal zone lymphomas are divided into MALT lymphomas, nodal marginal zone lymphomas and splenic marginal zone lymphomas. MALT lymphomas are the most common type and occur predominantly in the stomach. In patients with gastric MALT lymphoma with *Helicobacter pylori*, eradication of the infection will often lead to a clinical remission. However, the presence of the t(11;18) translocation predicts a higher chance of treatment failure and increased risk of relapse. For patients with localized gastric MALT lymphoma who do not achieve complete remission following antibiotic use, radiotherapy is usually curative. For advanced MALT lymphoma, chemotherapy plus rituximab is superior to the use of either treatment alone. Patients with nodal marginal zone lymphoma are usually given chemoimmunotherapy. Splenic marginal zone lymphoma typically presents with splenomegaly, and blood and bone marrow involvement. Patients with concomitant hepatitis C virus infection might respond to eradication of the virus. For other patients with symptomatic disease, single-agent rituximab can lead to clinical remission and is a good option. In patients with advanced stage disease, bulky abdominal nodes and constitutional symptoms bendamustine and rituximab are recommended [41].

6.2.5 Small Lymphocytic Lymphomas/Chronic Lymphoid Leukemia

Small lymphocytic lymphoma/chronic lymphoid leukemia constitute a disease spectrum. Patients with SLL present with hepatosplenomegaly and lymphadenopathy. SLL with peripheral blood monoclonal B lymphocytosis (>5000/μL) is termed as chronic lymphocytic leukemia. The treatment approaches are hence similar for both these conditions, which include wait-and-watch policy, chemoimmunotherapy, purine analog-based chemotherapy, targeted therapy including ibrutinib, venetoclax, etc. or a combination of these.

6.2.6 Follicular Lymphoma

The long-term survival in these patients closely approaches that of the normal population especially in the rituximab era. Many patients will die with but not from their follicular lymphoma or its complications; hence, long-term toxicities and quality of life improvement should be the primary objectives of treatment in follicular lymphoma.

Traditionally, grades 1 to 3A are considered histologically low-grade FL, while 3B is treated as an aggressive lymphoma. Early stage includes stage I and II follicular lymphoma, can be managed by RT alone with curative intent [42]. Radiation therapy (RT) to the limited disease in this population achieves good local control, and nearly half of these patients remain disease free [43]. Patients with non-contiguous, multifocal or bulky stage II disease should be managed as advanced stage disease. For low tumor burden advanced stage disease, active monitoring ("watch and wait") may be considered without adversely affecting long-term outcomes [44]. The GELF criteria can help identify those patients with FL in whom immediate therapy, rather than a watch-and-wait approach, is more appropriate. However, clinical judgment should be given more precedence over mere presence of one or two GELF criteria (Table 4).

Chemoimmunotherapy remains established first-line treatment for symptomatic advanced stage follicular lymphoma [41]. Rituximab maintenance following induction therapy remains an option for PFS advantage but there was no benefit in overall survival or quality of life [45].

Table 4 GELF criteria

Bulky disease: nodal/extranodal tumor mass >7 cm diameter or ≥3 nodal sites, each >3 cm diameter
Symptomatic splenomegaly
Organ compression; pleural effusion or peritoneal ascites
Elevated lactate dehydrogenase or elevated serum β2 microglobulin levels
B symptoms: unexplained fever >38 °C; drenching night sweats; or loss of >10% body weight within 6 months
Lymphocyte count $>5.0 \times 10^9$/L
Cytopenias (granulocytes $<1.0 \times 10^9$/L; platelets $<100 \times 10^9$/L)

6.2.7 Peripheral T-Cell Lymphomas

Mature T-cell lymphomas, such as peripheral T-cell lymphomas, are much less common than their B-cell counterparts but have as many subgroups, which makes clinical trials difficult; hence, treatment guidelines are seldom based on the results of randomized trials. Accurate diagnosis remains an issue. No standard therapy exists for patients with peripheral T-cell lymphoma not otherwise specified. These patients have traditionally received regimens such as CHOP and receive an autologous hematopoietic stem-cell transplant during initial remission. However, some studies have not shown a definite benefit from the incorporation of an anthracycline in the treatment regimen for patients with peripheral T-cell lymphoma.

Specific subtypes of peripheral T-cell lymphoma need attention. For patients with ALK-positive anaplastic large T-cell lymphoma have the best outcome with an anthracycline-containing regimen such as CHOP or CHOEP [46]. Patients with ALK-positive anaplastic T-cell lymphoma have a better outcome than those with ALK-negative anaplastic T-cell lymphoma, but this improved outcome is perhaps partly age-related, and older patients with either ALK-positive or ALK-negative anaplastic T-cell lymphoma seem to have nearly the same outcome [47]. Patients with localized extranodal NK–T-cell lymphoma presenting in the nose or nasal sinuses can be managed majority of times with chemoradiotherapy. These patients seem to be particularly sensitive to chemotherapy regimens that include methotrexate and L-asparaginase [48]. Peripheral T-cell lymphomas expressing CD30 respond to the antibody conjugate brentuximab vedotin. Brentuximab vedotin is now being incorporated into front-line regimens and usually substitutes for vincristine in the CHOP regimen. ALK-positive anaplastic T-cell lymphoma can also respond to the ALK inhibitor crizotinib. Other chemotherapeutic agents such as pralatrexate, romidepsin, belinostat and alisertib all have activity in peripheral T-cell lymphomas and can be used in patients with relapsed or refractory disease.

7 Management of Hodgkin Lymphoma

HL is classified into three subgroups which has prognostic as well as therapeutic significance in management.

I. Early stage (stage I and II)
    (a) Favorable
    (b) Unfavorable
II. Stage II B bulky (treated as advanced disease)
III. Advanced disease (stage III and stage IV)

7.1 Early Stage Favorable

Treatment strategies for early stage HL have evolved from radiation therapy alone to combine modality and now chemotherapy alone approach in PET era. Previously, extended field radiation was considered the standard therapy. NCIC group in their first randomized clinical trial had shown that subtotal radiation therapy (±ABVD) versus ABVD (4–6 cycles) has similar rates of freedom from disease progression (87% and 92%, respectively). Though radiation techniques used were primitive in this study, the outcome with chemotherapy alone arm was 90% at 12 years [49].

In early stage favorable disease, GHSG HD10 study group randomized between two/four cycles of ABVD chemotherapy and 20/30 Gy IFRT in 2 × 2 factorial design with four arms early favorable group. There was no difference between the four groups with respect to their progression-free survival and overall survival. Regards response to therapy, progression-free and overall survival. After this study results, ABVD for two cycles followed 20 Gy RT became standard of care in early favorable HL [50]. PET-adapted approach was used in HD16 trial to omit radiation in patients who were PET CR after two cycles; however, there was significant loss in tumor control in chemotherapy alone arm (5-year PFS, 93.1% [95% CI, 90.7–95.5%] vs. 80.9% [95% CI, 72.2–89.7%]; $P = 0.0011$) when Deauville score of 4 was used as a cutoff for positivity [51]. UK RADAR study is currently exploring the use of brentuximab with AVD in early favorable disease with an intention to omit radiation.

7.2 Early Unfavorable

Early stage unfavorable HL includes all patients with Ann-Arbor stage I or II disease and the presence of at least one risk factor (Table 5). Combined modality treatment (chemoradiation) remains the standard of care for early unfavorable HL. Number of ABVD cycles and dose of radiation is well established from GHSG HD11 trial. This trial again had four arms with 2 × 2 factorial design based on number of type of chemotherapy (ABVD/BEACOPP) and radiation dose (20 vs. 30 Gy). All four arms had similar freedom from disease progression. With prolonged follow-up in HD 11 study, there was no difference in progression-free survival between ABVD and BEACOPP when consolidated with 30 Gy radia-

Table 5 Risk stratification of early Hodgkin lymphoma

Risk factors	EORTC	GHSG	NCIC/ ECOG
Large mediastinal mass (>1/3)	Yes	Yes	No
Histology other than LP/NS	No	No	Yes
Age	≥50	No	≥40
Extranodal disease	No	Yes	No
ESR ≥50 mm/h without B symptoms or ≥30 mm/h with B symptoms	Yes	Yes	Yes
Number of nodal area involved	≥4 nodal areas	≥3 nodal areas	≥4 nodal areas

LP lymphocyte predominance, *NS* nodular sclerosis

tion therapy (HR, 1.1; 95% CI, 0.7–1.5; $P = 0.8$) [52]. However, in GHSG HD14 trial, an intensified chemotherapy schedule consisting of two cycles of escalated BEACOPP followed by two cycles of ABVD and 30 Gy IFRT (2 + 2) was more effective than four cycles of ABVD [53].

7.3 Early-Stage Risk/Response-Adapted Frontline Therapy

In the PET era, there were attempts to de-escalate therapy by omitting radiation using response adaption and replacing with more cycles of chemotherapy [54]. Two major trials were designed based on this principle-H10 trial (EORTC/LYSA/FIL) and the UK NCRI RAPID trial [55]. H10 trial compared in both early favorable and early unfavorable HL in a standard arm of ABVD + RT vs. the experimental arm which was driven by interim PET response (after two cycles of ABVD). Early PET-2 identified two risk population. First, one early PET-positive group where BEACOPP improved progression-free survival (HR 0.42 95% CI = 0.23–0.74); however, overall survival benefit was of borderline significance (HR 0.52 95% CI = 0.19–1.07). In PET-negative cohort H10 failed to demonstrate noninferiority of progression-free survival in no RT arm in both the subgroups. However, in early unfavorable HL, difference between noninferiority margin and upper boundary of CI was marginal. Hence, six cycles of ABVD remain an acceptable alternative in clinical situations where radiotherapy needs to be avoided.

In the UK NCRI RAPID trial, early-stage HL patients (defined as stage I–IIA and nonbulky disease) with a PET negativity after three ABVD cycles were randomized either to 30 Gy IFRT or to observation only [56]. Those with a positive PET (defined as DS-3, 4 and 5) were treated with one additional ABVD cycle followed by 30 Gy IFRT. Results suggested inferior PFS in chemotherapy alone arm as compared to CMT arm (3-year PFS 97.1% IFRT vs. 90.8% NFT), with a difference of 6.3%.

Though the difference didn't cross non inferiority boundary and the trial was reported as noninferiority of chemotherapy alone approach as opposed to CMT. In both trials PFS benefit was in the range of 6–12% in CMT arm as compared to chemotherapy-alone arm. The decision of response adapted therapy should be taken by multidisciplinary evaluation and counseling with each single patient affected with early-stage HL.

To summarize, two cycles of ABVD followed by IFRT is the standard of care in early favorable HL. Chemotherapy alone approach will lead 6–8% detriment in progression-free survival which needs to be discussed in a multidisciplinary team. Four cycles of ABVD followed by ISRT remain the standard of care for early unfavorable HL. Chemotherapy alone approach seems reasonable approach with marginal loss in tumor control and this decision should be taken in a multidisciplinary tumor board.

8 Advanced Hodgkin Lymphoma

Advanced Hodgkin lymphoma patients includes Ann Arbor stage III and IV along stage II B patients with bulky disease. Both ABVD and e-BEACOPP followed by RT to bulky sites and residual disease sites remains valid options in advanced Hodgkin lymphoma. There are several trials comparing ABVD and e-BEACOPP in advanced HL, all of them has consistently shown a PFS benefit of using e-BEACOPP regimen with overall survival remaining the same. A recent meta-analysis has shown OS benefit with e-BEACOPP (PFS: HR, 0.54; 95% CI, 0.45–0.64; OS: HR, 0.74; 95% CI, 0.57–0.97) [57]. This survival advantage with e-BEACOPP comes at the risk of secondary acute myeloid leukemia (AML) and myelodysplastic syndrome (MDS) as well as permanent sterility (90% in males and 50% in females). At relapse after ABVD, patients get second chance by salvage chemotherapy followed ASCT which nullifies the PFS advantage with e-BEACOPP. It can lead to overtreatment and unnecessary toxicity in significant proportion of patients who were anyways would have been cured with ABVD. Probably response-adapted therapy is the way forward in advanced HL, which selects out the poor performers with ABVD chemotherapy.

8.1 Response-Adapted Therapy in Advanced Hodgkin Lymphoma

Three trials addressed this question of response-adapted approach in advanced Hodgkin lymphoma. One after two cycles of ABVD, i.e., UK RATHL and other two after two cycles of e-BEACOPP, i.e., HD18 trial and AHL 2011 trial [58–60]. In the UK RATHL trial, de-escalation approach bleomycin could be omitted without compromising the efficacy if PET-2 is negative (DS-1, 2 and 3). In the PET-2 positive (DS 4 and 5), which was seen in 16% patients, escalation to e-BEACOPP has resulted in improved 3-year PFS and OS rates (67.5% and 87.8%, respectively), which is superior to historical controls.

In order to limit the toxicity of e-BEACOPP, HD 18 trial was designed where PET 2-negative (DS-1, 2) patients were de-escalated to two more cycles of e-BEACOPP. PET-2-positive group (DS-3, 4 and 5) were randomized to six cycles standard e-BEACOPP versus 6# Re-BEACOPP (total eight cycles in each arm). In PET-2-positive group, 5-year progression-free survival was 89.7% (95% CI 85.4–94.0). Addition of rituximab didn't make any difference. In PET-2-negative group, 5-year progression-free survival in deescalated arm (four cycles e-BEACOPP in total) was 92.2% (89.4–95.0) which was noninferior to the standard six cycles e-BEACOPP.

AHL 2011 is a noninferiority trial from France and Belgium where all patients received two cycles e-BEACOPP and underwent PET-CT. The PET-negative patients were switched over to four cycles of ABVD regimen, the PET-positive patients continued on BEACOPPesc for an additional four cycles. The trial proved noninferiority of this approach to standard four cycles e-BEACOPP from HD18 trial.

In conclusion, PET-directed therapy for de-escalation to AVD after negative PET-2 post two cycles of ABVD can be the standard of care. However, use of e-BEACOPP as escalation strategy may be justified by using HD18/AHL2011 approach when there is high IPS at baseline (IPS >3). RATHL approach can be employed in those who have low IPS at baseline to avoid overtreatment and limiting the toxicity.

8.2 Role of Radiotherapy in Hodgkin Lymphoma

The German Hodgkin Study Group (GHSG) HD10 study established two cycles ABVD, and a dose of 20 Gy IFRT is standard of care in early favorable HL. In unfavorable disease, 30 Gy was needed if the standard ABVD regimen was used as opposed to escalated BEACOPP regimen where 20 Gy was adequate. For advanced stage HL, RT didn't improve outcome if added in CR (by CECT) after full systemic chemotherapy. However, it did show benefit in those who remained in PR (partial response) after the end of systemic chemotherapy [61]. However, the role of RT in patients with bulky disease was not clear in the PET era. A prospective randomized study from Italy (GITIL/FIL HD0607 trial) has shown that consolidative RT can be safely omitted in patients who base line bulky node (defined by size ≥5 cm) and attained CMR by end of treatment PET [43]. The GHSG demonstrated in the HD15 trial that after intensive chemotherapy with escalated BEACOPP, consolidative RT should be given in patients with lesions more than 2.5 cm and are FDG avid [43].

8.3 Long-Term Complications

Hodgkin lymphoma survivors are at increased risk of developing long-term side effects, ranging from direct damage to organ function to second malignancies. Relapse of Hodgkin lymphoma remains the main cause of morbidity and mortality for initial 10 years after treatment. The cumulative incidence of mortality due to cardiovascular diseases and second malignancy exceeds to the disease-related mortality beyond 10 years of treatment. Hence, long-term follow-up plan of these patients should incorporate tools to assess risk factors for cardiovascular diseases.

Abbreviations

aCML	Atypical chronic myeloid leukemia
AML	Acute myeloid leukemia
CML	Chronic myeloid leukemia
CMML	Chronic myelomonocytic leukemia
DIPSS	Dynamic IPSS
ESA	Erythropoiesis-stimulating agents
ET	Essential thrombocythemia
FN	Febrile neutropenia
HMA	Hypomethylating agents
IPSS	International Prognostic Scoring System
JMML	Juvenile myelomonocytic leukemia
MD-CMML	Myelodysplastic CMML
MDS	Myelodysplastic syndromes
MP-CMML	Myeloproliferative CMML
MPN	Myeloproliferative neoplasms
PMF	Primary myelofibrosis
PV	Polycythemia vera
WHO	World Health Organization

1 Introduction

Myelodysplastic syndromes (MDS) and myeloproliferative neoplasms (MPN) are clonal hematopoietic disorders that have distinct clinical features, bone marrow morphology, flow cytometry and cytogenetic and molecular features. The MDS are a diverse group of bone marrow failure syndromes characterized by peripheral blood cytopenias and an increased risk of transformation to acute myeloid leukemia (AML) [1]. On the other hand, MPN are disorders characterized by clonal proliferation of myeloid precursors leading to marrow stromal changes and extramedullary hematopoiesis [2]. Some patients have a mix of features of MDS and MPN; these are overlap syndromes between MDS and MPN. In the current 2016 World Health Organization (WHO) classification, the entities in the overlap syndromes include chronic myelomonocytic leukemia (CMML), juvenile myelomonocytic leukemia (JMML), atypical chronic myeloid leukemia (aCML), and MDS/MPN unclassifiable. In addition to this, a provisional entity MDS/MPN with refractory anemia with thrombocytosis (MDS/MPN-RA-T) has also been included in this 2016 classification [3]. In this chapter, we discuss MDS, MPN and overlap syndromes. JMML is a pediatric disease and will not be discussed here.

2 Epidemiology

In 2000, the World Health Organization reclassified MDS from disorders with uncertain malignant potential to malignant, and following this, in 2001, MDS became reportable in the United States [4]. According to estimates from the SEER database, the age-adjusted incidence rate for MDS was 3.6 per 100,000 population in 2001. From that, it reached to a maximum of 5.1 in 2007 and remained at the same level till 2010. Subsequently, there was a slight decline to 4.7 in 2011

[4, 5]. Several western studies have consistently reported the median age to be >60 years [4]. Although reliable estimates of incidence are unavailable from India, reports do suggest that the median age is probably lower [6]. A study from AIIMS reported the median age to be 48 years [6] and another study from another institute reported the same as 55 years [7]. Although the precise reasons for this are unclear, there is speculation that this is probably because of biological differences [6].

Similar to MDS, MPN is also a disease of the elderly, with the median age being >60 years in most European and American studies [8, 9]. According to available data, the incidence of primary myelofibrosis (PMF), polycythemia vera (PV) and essential thrombocythemia (ET) ranges from 0.1 to 1, 0.4 to 2.8 and 0.3 to 1.7 per 100,000 per year, respectively. Although reliable epidemiology data from India are lacking, one hospital-based study showed that 0.01% of patients attending out-patient department of a general hospital had MPN [10]. Additionally, there is some data to suggest that, just like MDS, MPN also occurs at an earlier age. One study suggests that the median age is 44 and 53 years for JAK2-negative and JAK2-positive MPN, respectively [11]. Similarly, another study showed the mean age to be 45 in all patients with MPN other than CML [12].

Among the overlap syndromes, CMML is the commonest one in adults. The others are essentially rare illnesses [3].

3 Clinical Presentation

Patients with MDS present with symptoms associated with cytopenias (anemia being the most common), although a fraction of them can be asymptomatic at diagnosis. Both in Western and Indian studies, fatigue is the most common presenting symptom and is present in approximately 90% of patients [13, 14]. Breathlessness on exertion is present in more than one-third of patients [14]. Fever and bleeding manifestations are present in about 20–25% patients at time of diagnosis [13, 14]. About one-third patients have weight loss at the time of diagnosis [13]. Hepatosplenomegaly or lymphadenopathy is unusual and is present in <5% of patients [14]. If significant organomegaly or lymphadenopathy is present, diagnosis other than MDS should be considered.

The presentation of patients with MPN depends on the particular disease entity. Common symptoms in patients with polycythemia vera include headache, facial flushing and pigmentation. Fatigue, weakness, anorexia, weight loss and abdominal discomfort are common in patients with myelofibrosis. Abdominal discomfort is common in essential thrombocythemia. In contrast to MDS, nearly 80% patients with MPN have splenomegaly and about 15% have hepatomegaly [12]. Arterial and venous thrombotic events are most common in ET followed by PV, and are relatively uncommon in IMF. In general, the incidence of thrombotic events ranges from 1.6% to 2.2% during the early course of MPN [15].

4 Evaluation, Work-Up and Risk Stratification

The evaluation of any patient with suspected MDS or MPN (or overlap syndromes) begins with a history and physical examination. Careful attention to patient's symptoms is crucial because, often therapy is guided by the symptoms. Also, it is crucial to record the comorbid illnesses, performance status and physical findings—these are important parameters in deciding treatment and serve as the baseline for response evaluation (e.g., spleen size, hepatomegaly).

The laboratory evaluation of these patients begins with examination of complete blood counts (including reticulocyte count) and a peripheral smear (and also serum chemistries, electrolytes, coagulation profile, blood grouping, viral markers, nutritional work up as may be appropriate and ACSO, LDH and EPO levels where indicated). These baseline parameters help in risk stratification and are also important in response evaluation. This should be accompanied by bone marrow examination. Bone marrow examination forms the cornerstone of establishing the diagnosis of these disorders. Marrow evaluation should include marrow aspirate for morphology, flow cytometry (in those with suspected MDS), cytogenetic evaluation (including conventional karyotyping), molecular analysis and a bone marrow biopsy [16–18].

A detailed discussion of the blood and marrow morphologic findings is beyond the scope of this chapter; however, in a nutshell, it consists of dysplastic changes in the erythroid, myeloid and megakaryocytic lineage. To be relevant, dysplastic changes should be present in at least 10% nucleated cells of a particular lineage. Assessment of marrow (and peripheral blood) blast percentage is crucial in classification of MDS; at least 200 cells on peripheral blood film and at least 500 cells on marrow smears should be counted. Marrow cellularity should be assessed and may have some role in treatment selection (e.g., immunosuppressive therapy for hypoplastic MDS). Flow cytometry characteristically shows multiple immunophenotypic abnormalities. The ELN guidelines recommend obtaining a flow cytometry in all cases of suspected MDS. Cytogenetic analysis should include conventional karyotyping on at least 20 metaphases. Interphase FISH for recurrent abnormalities is useful in cases with inadequate metaphases or in those with normal karyotype. The FISH panel used at our center includes evaluation for deletion 20q, trisomy 8, deletion 5/5q and deletion 7/7q. It is important to note that among all the prognostic factors, cytogenetic abnormalities carry the highest weightage. For the purpose of prognostic scoring, the IPSS-R score (see below) assigns each cytogenetic abnormality to a risk group ranging from very good, good, intermediate, poor to very poor. This grouping can be found in several publications (and can be easily referenced online also). Although not mandatory currently (and currently not part of the risk stratification schemes), molecular analysis is becoming more and more relevant. Somatic mutations may be helpful in proving clonality especially when cytogenetics is noncontributory; many somatic mutations carry some prognostic significance. Additional work up may be indicated in some patients (e.g., all young patients with MDS should undergo evaluation for underlying Fanconi's anemia and evaluation for PNH clone should be done in patients with hypocellular marrow). With this information, patients with MDS should be classified according the WHO classification into distinct disease categories. The WHO classification system puts MDS into distinct diagnostic categories; these different entities differ in their risk of progression to AML and in their prognosis. In addition to categorization, the information obtained from above work up is also adequate to risk stratify patients with MDS. There are several risk stratification systems of which the International Prognostic Scoring System (IPSS) and revised IPSS (IPSS-R) are the most important. The IPSS categorizes patients into four prognostic categories (low, intermediate 1, intermediate 2 and high risk) and IPSS-R into five categories (very low, low, intermediate, high and very high-risk groups). Both these scoring systems are based on marrow blast percentage, cytopenias and cytogenetic abnormalities. These risk groups differ in their risk of progression to AML and in their overall survival. In addition, risk stratification is extremely important in planning therapy (as discussed below). From a therapeutic perspective, low-risk IPSS and intermediate 1 IPSS are often clubbed together as low risk MDS; intermediate 2 and high-risk IPSS are clubbed together as higher risk MDS [16, 17, 19, 20]. More recently, a new risk stratification system, the Molecular International Prognostic Scoring System (IPSS - M), which incorporates mutational analysis data has been devised for MDS.

Similar to MDS, the classification of patients with MPN also depends on clinical parameters, marrow findings and molecular characteristics. The marrow is hypercellular in MPN (except in the burnt-out phase of PMF) and marrow biopsy is extremely crucial for assessment of marrow cellularity and reticulin or collagen fibrosis. Bone marrow examination is not mandatory for confirmation of diagnosis of polycythemia vera; however, it is recommended to be done in all suspected cases. For suspected PMF and ET, marrow examination is essential to establish the diagnosis. CML should be excluded by cytogenetic and molecular in all suspected cases of CMPD since it has an entirely different treatment and prognosis. Molecular analysis for MPN should include JAK2 V617F, JAK2 exon 12 mutation, CALR mutations and MPL mutations; many more have been recently described. A prognostic significance of some of these mutations is beginning to be unraveled. Just like MDS, several prognostic scoring systems also exist for PMF. One of the early scoring systems was the Lille score, which has largely been replaced by the IPSS. The IPSS for PMF takes into consideration age, constitutional symptoms, hemoglobin, WBC count and peripheral blood blasts, and divides patients with PMF into four different risk categories (low, intermediate 1, intermediate 2 and high-risk groups). More recently, dynamic IPSS (DIPSS) and DIPSS plus scoring systems have been used. While the IPSS score is useful at predicting survival and the risk of leukemic transformation at the time of diagnosis, the DIPSS score (based on the same factors as the IPSS score) can been used for estimating the prognosis from any time point in the course of illness. The DIPSS score is further refined by adding platelet count, red cell transfusion need and karyotypic abnormalities to form the DIPSS plus score. More recently, a prognostic score incorporating the molecular abnormalities has also been proposed (MIPSS 70 and MIPSS 70 plus). Similar to MDS, the prognostic scoring in PMF also helps to guide treatment (see below) [2, 18, 21–23].

In contrast to PMF, the risk stratification in PV and ET primarily depends on age and prior history of thrombosis (and also platelet count to some extent in ET). However, just like PMF, the risk category does help in deciding treatment [18].

The work up remains the same for overlap syndromes. Patients with CMML can be classified into myelodysplastic CMML (MD-CMML) or myeloproliferative CMML (MP-CMML). Patients with CMML with WBC count of >13,000/cumm are classified as MP-CMML. These have a better prognosis compared to MD-CMML. In addition, the blast percentage in the peripheral blood and bone marrow also affect the prognosis. The cut-offs used for segregating the prognostic groups are similar to those used for classification of MDS. In addition, at least 10 recurring mutations have now been identified in CMML with varying degrees of prognostic significance; of these ASXL1 mutations strongly confer an adverse prognosis. For the non-CMML overlap syndromes, although there are no well validated risk stratification systems for overlap syndromes, there is some data to show that older age at diagnosis, higher leukocyte count at diagnosis and SETBP1 mutation are adverse prognostic factors. Patients with these adverse prognostic features may be considered as high-risk patients [3, 24].

5 Principles and Guidelines for Management

The spectrum of therapies that can be offered in MDS, MPN and overlap syndromes ranges from watchful waiting to allogenic HSCT. The choice of therapy should be carefully made taking into consideration the symptoms, risk categorization, age, comorbid illnesses, and several other factors. Since allogenic HSCT is the only curative treatment, it should be offered to all young fit patients. However, HSCT may not be feasible in a sizeable proportion of patients, given that these disorders are typically seen in elderly patients (who may have many other coexisting comorbidities). In those patients in whom transplant is not feasible, the goals of management include minimizing the consider symptoms associated with the disease and maintaining the quality of life. It may be noted that although there are well defined response criteria published both for MDS and MPN, these are primarily intended to be used in clinical trials and not in routine clinical care [2, 25].

For MDS, cytopenias (predominantly anemia) need to be addressed. Supportive care is very important for all patients, in the form of transfusions, management of thrombocytopenia, prevention and management of infective episodes and iron chelation. Therapy with hypomethylating agents (HMA) or chemotherapy may be needed in some patients as discussed below. However, HMA and chemotherapy are not curative in MDS.

For MPN, important aspects of supportive care include treating symptomatic organomegaly, prevention and management of thrombosis and/or bleeding, and cytoreduction to prevent complications associated with hyperleukocytosis. JAK2 inhibitors (ruxolitinib and others) are useful in selected patients as discussed below. However, as is true for MDS, the only curative treatment for MPN is also allogenic stem cell transplant.

For overlap syndromes, the principles are essentially similar to those of MDS and MPN. Treatment should include management of anemia, treating symptomatic organomegaly, and control of counts. In addition, the drugs used for these syndromes are similar to those of MDS and MPN. However, there are also some novel agents in clinical trials [3].

6 Medical Management Options for MDS

Watchful waiting: Patients with lower risk MDS (see risk stratification above) often have indolent disease, low risk of progression to AML and long survival. Studies have shown that about half of these patients will die of causes unrelated to MDS [16]. Other studies have shown that life expectancy of elderly patients (>70 years) with refractory anemia or MDS with isolated del (5q) is similar to that of the general population [26]. Such studies provide evidence that, patients with lower risk MDS can be kept under a period of watchful waiting without active treatment. Current ELN recommendations suggest watchful waiting for patients with primary MDS low IPSS risk category and asymptomatic cytopenia.

For symptomatic patients with lower risk MDS, the primary goals of therapy are improvement of the symptoms associated with cytopenias and improvement of quality of life. Anemia is the most common cytopenia. For patients with lower-risk MDS and absence of del 5q, erythropoiesis-stimulating agents (ESA) are often the first-line therapy. These benefit about two-thirds of the patients. A detailed review of the ESA is beyond the scope of this chapter and excellent reviews can be found elsewhere. Patients with del 5q MDS often show resistance to ESA or short-lived responses, and in these patients, lenalidomide is chosen as the first-line therapy. Second-line agents for treatment of anemia include immunosuppressive therapy (antithymocyte globulin, cyclosporine, or both), lenalidomide (in those in whom it has not been previously used), erythroid maturation agents such as luspatercept or HMA. Immunosuppressive therapy often benefits those patients with lower risk MDS who have hypoplastic marrow and/or a small PNH clone, normal karyotype, no excess blasts and HLA-DR*15 genotype. Luspatercept mainly helps transfusion dependent patients with ringed sideroblasts who have failed ESA therapy. Packed cell transfusions are required in those who do not respond to any of these therapies. In patients requiring regular or frequent packed cell transfusions, iron chelation therapy should be considered as per standard guidelines [16].

Isolated neutropenia is rare in lower risk MDS, and it is even rare to need therapy. G-CSF or GM-CSF can be used for the treatment of febrile neutropenia (FN), along with broad spectrum antibiotics and other standard supportive therapy for FN. Isolated requirements of G-CSF or GM-CSF is very rare.

For patients with thrombocytopenia and lower risk MDS, danazol, and TPO receptor agonists (romiplostim and eltrombopag) are available agents. Either of these produces a clinical benefit in about 60–75% of the cases [16, 17, 27].

For patients with higher risk MDS (intermediate 2 and high-risk IPSS), hypomethylating agents (HMA) with or without venetoclax are an important treatment option and represent the most often used/preferred first-line therapy. HMAs (with or without venetoclax) can be used as sole therapy (along with supportive care) for patients considered unfit for transplant or those unwilling for transplant for various reasons, or they can be used as a bridge to transplant. Azacitidine is associated with improved overall survival compared to best supportive care (or low- or high-dose chemotherapy) and hence is preferred among the two agents. Decitabine has not been proven in randomized trials to improve survival but is often used interchangeably with azacitidine. Azacitidine and decitabine have not been compared head to head in randomized trials in this situation. Because responses to these agents are often delayed, these must be given for at least 4–6 cycles. For patients who benefit from HMAs, these are often continued till disease progression or toxicity [16]. Other options like low-dose chemotherapy or high-dose chemotherapy are not preferred as first-line options due to the lack of robust data supporting survival benefit and because of toxicities [16].

For patients who relapse after HMA or those who progress on HMA, the options are limited and their prognosis is dismal. Options like high-dose chemotherapy, low-dose chemotherapy or lenalidomide, use of the alternative HMA or combination of azacitidine with lenalidomide may be considered. In spite of any treatment offered, the prognosis of such patients remains poor [28]. Participation in clinical trials should be considered wherever possible.

The only curative treatment for MDS is allogenic stem cell transplant, and it is important that all young fit patients are offered this treatment. All potentially eligible patients should have their HLA typing done as soon as diagnosis is established. The long-term survival post allogenic stem cell transplant depends on multiple factors (including the IPSS risk group, type of transplant, degree of HLA match and others) and ranges from about 30% to 60% [17].

7 Medical Management Options for MPN

Medical management of patients with MPN depends on several factors—the particular MPN (PV vs. ET versus PMF), symptoms, age, risk of thrombosis, and other factors. Apart from conventional therapies, ruxolitinib represents a relatively recent major breakthrough in the treatment of these disorders. Several new agents are also in development, either alone or in combination with ruxolitinib. It is important to understand where to place ruxolitinib and the newer agents in the management of patients with MPN. A careful attention to patient's symptoms and priorities are very essential in clinical practice of these chronic disorders [18, 29].

For patients with PV, thrombosis represents a major risk and results in significant morbidities. The risk stratification of PV is based on risk of thrombosis and the aim of therapy is to reduce the risk of vascular complications. Life-style modifications to reduce the cardiovascular risk, and in particular smoking cessation should be considered for all patients [18]. For low-risk disease, phlebotomy (to maintain hematocrit target of 45%) and low-dose aspirin are recommended [18]. For selected patients with low risk—those with increasing counts, or those with worsening splenomegaly or those who are unable to tolerate phlebotomy, cytoreductive therapy may be needed. For high-risk disease, cytoreductive therapy in addition to aspirin and phlebotomy may be needed. Hydroxyurea is the preferred first-line cytoreductive agent in these patients [18, 30]. Second-line therapies in patients not tolerating or not responding to hydroxyurea include interferon and ruxolitinib [18, 29, 30]. Interferon is the agent of choice in pregnant females if required [18]. At present, the use of ruxolitinib should be restricted to patients with worsening splenomegaly or intractable pruritus or intolerance to hydroxyurea [30]. Ruxolitinib produces responses in 50–60% of such patients [31, 32].

For patients with ET, similar to those with PV, the risk stratification is based on the thrombotic risk, and again, as in PV, the aim of therapy is to reduce the risk of vascular complications. Observation alone is recommended for patients with very low risk disease. For those with low and intermediate risk disease, aspirin is recommended, particularly in the presence of vasomotor symptoms. Patients with high-risk disease need cytoreductive therapy in addition to aspirin. As with PV, hydroxyurea remains the drug of choice for these patients. Other agents which may be used in the second-line setting include anagrelide, interferon, busulfan or ruxolitinib. However, the use of these agents should be restricted to very selected patients [18, 29, 30].

In contrast to PV and ET, the risk stratification of PMF is different and is based on parameters like hemoglobin, absolute neutrophil and platelet count, marrow blast percentage, cytogenetics and molecular abnormalities [33]. Hydroxyurea is probably the most common agent used in the treatment of PMF and is useful in control of leukocytosis and thrombocytosis, and in reducing the spleen size. Additionally, it also probably improves constitutional symptoms, bone pains and pruritus. Interferon may be used and is probably more helpful earlier in the disease course. However, although interferon leads to control of counts, it probably does not reduce spleen size. Agents that may be helpful in the treatment of anemia include ESA, prednisolone, danazol and the IMiDs. Thalidomide, lenalidomide and more recently pomalidomide all have been used in PMF and have shown some benefit [34–36]. Among these three agents, low-dose thalidomide (in combination with prednisolone) is probably the most active. The activity of lenalidomide (in combination with prednisolone) and pomalidomide is very modest.

Ruxolitinib is a JAK1/JAK2 inhibitor and is the first approved targeted therapy in PMF. In addition to improving the symptoms and reducing the spleen size, ruxolitinib is also associated with improvement in survival. The reason behind the survival advantage is unclear. However, improvement in cachexia and decrease in systemic inflammation have been speculated as putative mechanisms. In addition, it is also speculated that long-term therapy might stop the progression of marrow fibrosis and it has been shown to decrease the mutant allele burden. It is likely that ruxolitinib when used in patients with low and intermediate-1 IPSS disease might lead to better long-term benefits. Several other agents (e.g., Panabinostat, interferon, danazol) are being tested in combination with ruxolitinib. Also, the role of ruxolitinib before stem cell transplant, and its impact on transplant outcomes are areas of study [28, 37, 38]. Several second generation JAK inhibitors are currently in development.

Allogenic HSCT is the only curative treatment for MPN and should be offered to all patients with intermediate-2 and high-risk PMF. It is also indicated in selected patients with intermediate-1 disease (e.g., those with transfusion-dependent anemia, adverse cytogenetics, ASXL1 mutation, triple-negative disease, etc.). Stem cell transplants in myelofibrosis carry a higher risk of transplant-related complications and death (compared to many other disorders), and a long-term survival is achieved in about 30–40% of patients [18, 29]. Allogenic stem cell transplant is not discussed further here and is discussed further in a separate chapter.

8 Medical Management Options for Overlap Syndromes

For overlap syndromes, similar to MDS and MPN, allogenic HSCT remains the only curative option. For CMML, the classification into MD-CMML and MP-CMML helps to guide treatment—the former are treated like MDS, the latter like MPN. For the non-CMML overlap syndromes, the treatment should include treatment of anemia, use of hydroxyurea (or interferon) when necessary, a trial of ruxolitinib when hydroxyurea fails and use of conventional chemotherapy in event of transformation to AML. In addition to these, there are some novel agents in clinical trials [3, 24].

9 Prognosis with Current Therapy

With the introduction of several new therapies and drugs, and with improvement in the outcomes and safety of stem cell transplantation, the outcomes of patients with MDS and MPN have significantly improved in the last two to three decades.

As is true for several other malignancies, the prognosis for patients with MDS and MPN depends on several disease related characteristics, and patient characteristics (e.g., performance status, comorbid illness, fitness for therapy, etc.).

With current therapies, the median survival of patients with MDS ranges from less than 1 year (for patients with very high revised IPSS risk group) to nearly a decade for patients with very low risk group [19]. Within each subgroup, additional factors like transfusion dependency, genetic mutations and other parameters also affect the outcomes. Similar to MDS, the survival of patients with PMF ranges from about 2 years (for patients with high IPSS risk group) to more than 10 years for those with low-risk disease [33]. As research reveals novel molecular prognostic markers in MDS and MPN, the prognostics schema is likely to be revised in the future. These may help to more accurately estimate the expected survival of individual patients with these disorders. The survival of patients with PV and ET treated with conventional therapy typically spans decades, and in many subsets (like low-risk ET) is similar to that of the general population [29].

As stated previously, the only curative treatment for both MDS and MPN is allogenic stem cell transplant. Long-term cure with allogenic stem cell transplant occurs in 30–60% of patients with MDS and about 30% to 40% patients with PMF.

10 Treatment of Relapsed Refractory Disease and Palliative Care Measures

Patients with relapsed MDS including those with progress to AML and patients with MF who do not respond to usual therapy or transform to AML represent a major therapeutic challenge. Unfortunately, there are no good salvage therapy options for these patients, and their prognosis remains dismal. Options for these patients are discussed under medical management (see above) under individual disease entity. Even with transplant, the prognosis of such patients is guarded; a long-term survival is achieved only in about 10–15% cases. Wherever feasible, enrollment in clinical trials should be considered. With several targeted drugs, molecular profiling of such patients is likely to help identify patients who may benefit from specific targeted therapy. Several such therapies are in the pipeline; several new trials are anticipated. Novel drugs are likely to change the dismal outcome of these patients; however, this may not happen in the near future.

11 How We Do It at TMC

At our center, we have a hematolymphoid disease management group which caters only to patients with hematolymphoid malignancies. This group consists of medical oncologists, radiation oncologists, pathologists, hematopathologists, radiologists and nuclear medicine experts, molecular pathologists, and other allied staff like social service staff, etc. This group has been functional since 2007.

All patients with suspected MDS and MPN are evaluated by the members of this group. The basic work up consists of blood and marrow examination as outlined before. Supportive care as required is provided to all patients during the diagnostic work up. Additional work up is requested if required based on the results of the initial work up. After diagnosis, risk stratification is done. We follow the revised IPSS system for MDS and IPSS system for myelofibrosis.

In general, the management follows the guidelines as mentioned above. All young fit patients are evaluated by our transplant team for the possibility of undergoing this curative treatment. For those who are unfit for transplant or are unwilling for the same (including those in whom it is not feasible due to logistic or financial reasons), we treat by medical management as discussed above. For higher risk MDS, we start patients on HMA (with venetoclax whenever feasible). Although we prefer azacitidine, the two are often used interchangeably (more often due to issues with the availability and cost). We evaluate response by a repeat marrow examination after 4–6 cycles of HMA, and in those who are responding, we continue the HMA therapy usually for 12 months or longer. Standard supportive care is provided all throughout.

For MPN too, we follow the usual guidelines. Hydroxyurea is the standard first-line cytoreductive agent; ruxolitinib is reserved for those not responding to HU or progressing on HU or intolerance to HU. Again, just like MDS, all young and fit patients are offered HSCT.

Plasma Cell Dyscrasias

Prashant Tembhare, Goda Jayant Sastri,
and Bhausaheb Bagal

1 Introduction

Plasma cell neoplasms are a clonal proliferation of plasma cells that are terminally differentiated B-cells characterized by immunoglobulin secretion. It includes a wide spectrum of plasma cell disorders, from asymptomatic monoclonal gammopathy of unknown significance (MGUS) and smoldering myeloma (SMM) to symptomatic multiple myeloma (MM), to plasma cell leukemia (PCL). A small proportion of plasma cell neoplasms (approximately 5–6%) will present as a solitary plasmacytoma (SP), either in bone or extramedullary tissues. Definitions and diagnostic criteria for each category of plasma cell neoplasms are given in Table 1.

The majority of plasma cell tumors are diagnosed as multiple myeloma (MM) and usually affect older adults. It is a multifocal neoplasm originating in the bone marrow and is characterized by clonal proliferation of malignant plasma cells in the bone marrow, secretion of monoclonal protein (also known as M-protein) in the blood or urine, and multiple organ dysfunction [1]. It evolves from a premalignant condition clinically recognized as MGUS [2–4].

The first documented case of MM was reported by Solly in 1844 in a 39-year-old woman, Sarah Newbury, and approximately a year later it was followed by a well-described case of Thomas Alexander McBean "a highly-respectable tradesman," 45 years of age [5]. In 1873, J. von Rustizky introduced the term "*multiple myeloma*" first time, and 16 years later Otto Kahler described the disease and hence, was also referred as "Kahler's disease" [5, 6]. Since then the diagnosis and treatment of multiple myeloma have changed dramatically. There has been a huge improvement in our understanding of the pathogenesis of myeloma leading to the discovery of highly specific biomarkers which are routinely practiced in the in the management of MM. Over the years, the staging system has been revised multiple times to combine measures of tumor burden, biology and underlying genetics of the disease. Recent advances in therapy like high dose chemotherapy with autologous stem cell transplant and availability of novel drugs like protease inhibitors and immunomodulators have resulted in a marked improvement in overall survival [7].

Table 1 Diagnostic criteria of plasma cell disorders

Plasma cell disorder	Diagnostic criteria [11, 17]
Non-IgM MGUS	• Serum monoclonal protein (non-IgM type) <30 g/L • Clonal bone marrow plasma cells <10% • The absence of end-organ damage, i.e., CRAB features or amyloidosis
IgM MGUS	• Serum IgM monoclonal protein <30 g/L • Bone marrow lymphoplasmacytic infiltration <10% • No evidence of anemia, constitutional symptoms, hyperviscosity, lymphadenopathy, hepatosplenomegaly, or other end-organ damage that can be attributed to the underlying lymphoproliferative disorder
Light-chain MGUS	• Abnormal FLC ratio (<0.26 or >1.65) • Increased level of the appropriate involved light chain (increased κ FLC in patients with a ratio >1.65 and increased λ FLC in patients with ratio <0.26) • No immunoglobulin heavy chain expression on immunofixation • The absence of end-organ damage, i.e., CRAB features or amyloidosis • Clonal bone marrow plasma cells <10% • Urinary monoclonal protein <500 mg/24 h
SMM	Both criteria must be met: • Serum monoclonal protein (IgG or IgA) ≥30 g/L or urinary monoclonal protein ≥500 mg/24 h and/or clonal bone marrow plasma cells 10–60% • The absence of end-organ damage, i.e., CRAB features or amyloidosis
MM	Clonal bone marrow plasma cells ≥10% or Biopsy-proven bony or extramedullary plasmacytoma and Any one or more of the following myeloma defining events: *Myeloma defining events*: • Evidence of end-organ damage (**CRAB** features) that can be attributed to the underlying plasma cell proliferative disorder, specifically: – *Hypercalcaemia*: serum calcium >0.25 mmol/L (>1 mg/dL) higher than the upper limit of normal or >2.75 mmol/L (>11 mg/dL) – *Renal insufficiency*: creatinine clearance <40 mL/min or serum creatinine >177 μmol/L (>2 mg/dL) – *Anemia*: hemoglobin value of >20 g/L below the lower limit of normal, or a hemoglobin value <100 g/L – *Bone lesions*: one or more osteolytic lesions on skeletal radiography, CT, or PET-CT Any one or more of the following biomarkers of malignancy: – Clonal bone marrow plasma cell percentage ≥60% on BMA or BMBx – Involved: uninvolved serum free light chain ratio ≥100 (using Freelite assay, UK) – >1 focal lesions on MRI studies with a minimum of 5 mm
Plasma cell leukemia	Presence of 5% or more circulating plasma cells in peripheral blood smears in patients otherwise diagnosed with symptomatic multiple myeloma (IMWG 2021)
Solitary plasmacytoma	• Biopsy-proven solitary destructive lesion of bone or soft tissue mass of clonal plasma cells • The absence of clonal plasma cells in bone marrow biopsy and aspirate • Normal skeletal survey and MRI (or CT) of the spine and pelvis (except for the primary solitary lesion) • The absence of end-organ damage, i.e., CRAB features
Solitary plasmacytoma *with minimal marrow involvement*	• Biopsy-proven solitary lesion with evidence of clonal plasma cells • Clonal bone marrow plasma cells <10% • Normal skeletal survey and MRI (or CT) of the spine and pelvis (except for the primary solitary lesion) • The absence of end-organ damage, i.e., CRAB features
POEMS syndrome	Mandatory criteria • **P**olyneuropathy • **M**onoclonal plasma cell proliferative disorder (almost always λ) Any one of the following three other major criteria: • Sclerotic bone lesions • Castleman's disease • **E**levated levels of VEGF Any one of the following six minor criteria: • **O**rganomegaly (splenomegaly, hepatomegaly, or lymphadenopathy) • Extravascular volume overload (edema, pleural effusion, or ascites) • Endocrinopathy (adrenal, thyroid, pituitary, gonadal, parathyroid, pancreatic) • **S**kin changes (hyperpigmentation, hypertrichosis, glomeruloid haemangiomata, plethora, acrocyanosis, flushing, white nails) • Papilloedema • Thrombocytosis/polycythaemia
Systemic AL amyloidosis	• Presence of an amyloid-related systemic syndrome (e.g., renal, liver, heart, gastrointestinal tract, or peripheral nerve involvement) • Positive amyloid staining by Congo red in any tissue (e.g., fat aspirate, bone marrow, or organ biopsy) • Evidence that amyloid is light-chain-related established by direct examination of the amyloid using mass spectrometry-based proteomic analysis, or immunoelectron microscopy • Evidence of a monoclonal plasma cell proliferative disorder (serum or urine monoclonal protein, abnormal free light-chain ratio, or clonal plasma cells in the bone marrow)

2 Incidence and Epidemiology in India and Global

2.1 Monoclonal Gammopathy of Unknown Significance and Smoldering Myeloma

MGUS affects approximately 3% of Caucasians over the age of 50 years with 1% average annual risk for progression to MM. The usual sequence of development of monoclonal gammopathies is MGUS progress to smoldering multiple myeloma (SMM) and then MM, which may progress finally to PCL [7]. Approximately 25% of patients with MGUS develop MM after a follow-up of more than 20 years. However, SMM carries a higher risk of progression to frank multiple myeloma (10% per year the first 5 years) compared with MGUS [2–4, 8–10].

2.2 Multiple Myeloma

MM is the second most common adult hematologic malignancy accounting for approximately 1–1.7% all of the cancers and 10–13% of hematologic neoplasms (Fig. 1) [1, 11]. The incidence of MM varies in different parts of the world, and it has been reported higher in western countries like the United States, European countries, Australia, etc. but is lesser in Asian countries [7, 12]. The estimated world-wide 5-year prevalence is approximately 230,000 patients [13]. The median age of patients at diagnosis is approximately 66–70 years with 37% of patients younger than 65 years of age and is extremely rare in those less than 30 years of age with a reported frequency of 0.02–0.3% [12]. Although robust data on the incidence of MM in India is lacking, considering the probability of 0.1% of the development of MM in elderly, it affects a large group of population [14]. The annual incidence of MM in the Indian population is considered in between 0.35 and 0.96 per 1,00,000 population [7]. The median age of MM patients is approximately a decade younger than western population, i.e., 56 years (range, 29–85 years) [15, 16].

2.3 Solitary Plasmacytoma

SP is an uncommon lesion and accounts for only 1–2% of plasma cell neoplasms (Figs. 2 and 3). Males are affected more than females and the median patient age at diagnosis is approximately 55 years [17]. Although the incidence of SP in India is not known, the median age is 53 years and M:F ratio of 2.2 [18].

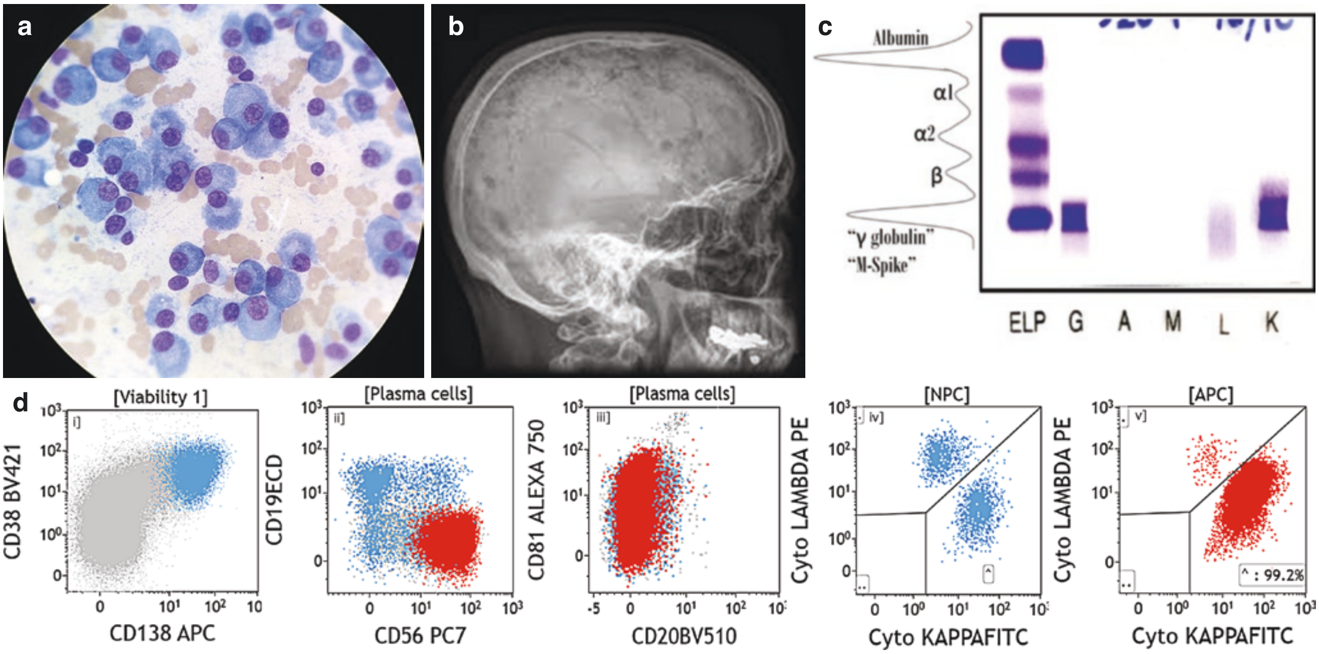

Fig. 1 (**a**) Microscopic picture (oil immersion, 100×) of bone marrow aspirate smear with markedly increased plasma cells in a case of multiple myeloma. (**b**) X-ray of skull with multiple lytic lesions. (**c**) Results of serum protein electrophoresis and immunofixation demonstrating "M-spike" with IgG-Kappa type M-protein. (**b**) Corresponding axial CT image showing the nasopharyngeal extramedullary plasmacytoma. (**c**) Corresponding axial PET image showing increased uptake in the nasopharyngeal extramedullary plasmacytoma

2.4 Systemic (AL) Amyloidosis

It is a relatively uncommon disease with an incidence of 3–5 cases per million population in the USA, approximately one per 100,000 population in UK, and 3.2 per million person-years in Sweden [19].

3 Etiology and Pathogenesis

The cause of plasma cell neoplasm (PCN) is still unknown. Several studies have evaluated potential risk factors responsible for development that included exposure to radiations, pesticides, hair dyes, benzene and petroleum products, etc. However, a little evidence is available to support a causal relationship with the development of PCN [7, 20, 21]. PCN are as such not genetic diseases; however, a few familial cases highlighting genetic inheritance for this disease have been reported [22–25].

MM is a characterized by uncontrolled proliferation of malignant plasma cells that are derived from post-germinal-center B cells. Multistep genetic and microenvironmental changes lead to the transformation of these cells into a malignant neoplasm. In germinal centers of lymphoid organs, B cells undergo affinity maturation, somatic hypermutation, and isotype class-switch recombination that result in the production of antibodies with a high affinity for specific antigens [1, 26]. In a predisposed person, the process of somatic hypermutation and class-switch recombination leads to aberrant fusions of DNA and chromosomal translocations. Rarely, these translocations involve specific oncogenes that give cells a growth advantage leading to the development of clonal plasma cells which initially constitutes a premalignant condition, i.e., MGUS which progress to SMM and eventually multiple myeloma. Common translocations involve IGH region of genes on chromosome "Ch 14" and a set of recurrent partner genes, such as NSD2 (also known as MMSET) & FGFR3 [t(4;14)], MAF [t(14;16)], MAFB [t(14;20)], and Cyclin-D1 [t(11;14)] & Cyclin-D3 [t(6;14)] [7, 27]. Recently, MYC was identified as a deregulated factor in up to 50% of patients. Thus, chromosomal translocations are a possible initiating event for a subset of MM cases. Another possible genetic alteration that may be involved in the initiating events responsible for almost half of this disease is a hyperdiploidy (chromosomes >46), a frequent form of aneuploidy. The secondary genetic events associated with MM include genetic mutations like RAS genes (K-ras/N-ras), FAM46C, DIS3 TP53, and others [28–31]. These mutations can affect several cellular signaling pathways (NF-κB pathways and MAPK pathway) and alter the cell apoptotic and proliferation mechanism and may be involved in the disease progression of MGUS to MM [29, 32, 33].

Besides genetic factors, bone marrow microenvironment, and immune reconstitution also play a vital role in the pathogenesis of MM. The interaction between the proteins like vascular cell adhesion protein 1 (VCAM1), CXC-chemokine ligand 12 (CXCL12) expressed the on the cell surface of bone marrow stromal cells (BMSCs), osteoblasts, endothelial cells and proteins expressed on the myeloma cells like CXC-chemokine receptor type 4 (CXCR4), integrin results in the secretion of several cytokines and chemokines which creates a favorable environment for cell proliferation, migration, and inhibition of apoptosis for MM cells [34–39]. Additionally, macrophages also produce factors like IL-1β that interacts with BMSCs and induce IL-6 secretion [39, 40]. Likewise other cell types, including T cells, B cells, monocytes, and multiple myeloma cells, also produce IL-6, which promotes proliferation of multiple myeloma cells and resistance to apoptosis contributing to the progression of this disease [40]. Immune-cells like T-cells, NK cells, dendritic cells and myeloid-derived suppressor cells (MDSCs) also constitute an integral component of microenvironment and show quantitative as well as functional impairment with the advancement of disease through "antigen-specific T-cell tolerance" [41, 42]. Thus, pathogenesis and disease progression in MM is a multifactorial biological process that involves genetic, microenvironmental, and immunological factors.

Other plasma dyscrasias caused due to the proliferation of monoclonal plasma cells and secretion M-protein include systemic amyloidosis and POEM syndrome. Pathogenesis of POEM syndrome is not understood yet but is multiorgan affecting disease as a result of the paraneoplastic process associated with the monoclonal lambda plasma cell disorder and possibly caused by increased levels of proinflammatory cytokine milieu [43]. Systemic amyloidosis also referred as "AL amyloidosis" and is a result of the extracellular deposition of monoclonal immunoglobulin light chains that forms the amyloid [44].

4 Clinical Presentation

Clinical manifestations of the MM are primarily caused by neoplastic plasma cells and monoclonal protein and/or cytokines secreted by them. The common clinical manifestations of the MM include signs of end-organ damage, such as hypercalcemia (C), renal insufficiency (R), anemia (A), and/or bone disease (B) with lytic or pathological fractures [9]. These manifestations are collectively known as CRAB features. Although most of the MM patients are characterized by the secretion of a M protein, approximately 15–20% of patients are associated with only monoclonal free light chains secretion (also referred as "light chain myeloma"), and, in <3% of patients these cells secrete no monoclonal protein (also referred as "non-secretory myeloma") [10, 11].

The usual symptoms of MM include bone pain (e.g., back pain), weakness, fatigue, weight loss, recurrent infections, easy bruisability, and increased bleeding tendencies etc. These symptoms reflect manifestations of underlying lytic bone lesions, anemia, hypercalcemia, thrombocytopenia, and hypogammaglobulinemia. A study of 1027 MM patients from Mayo Clinic, Rochester, MN (USA) reported the frequency of clinical symptoms at presentation that included bone pain in 58%, fatigue (usually related to anemia) in 32%, weight loss in 24%, and other symptoms like paresthesia (5%), fever (0.7%), etc. [6]. A recent data of 3988 MM patients from the Swedish Myeloma Registry documented osteolytic lesions or compression fractures in 77%, anemia in 49%, impaired kidney function in 18%, and hypercalcemia in 13% patients [45].

Patients with POEMS syndrome usually present with clinical features related to polyneuropathy that includes weakness, numbness, and tingling in the legs and arms, organomegaly like hepato-splenomegaly and few times symptoms like fatigue, swelling in your limbs, sexual problems, those are caused by underlying endocrinopathy like diabetes, hypothyroidism, and problems with metabolism, etc. [43, 46]. The clinical presentations of AL amyloidosis diverse and depends on the organ of involvement [19, 47]. It usually affects the heart, kidneys, liver, spleen, nervous system and digestive tract. Severe forms of amyloidosis can lead to organ failure and ultimately death. The pathognomonic clinical presentation of AL amyloidosis includes a macroglossia and periorbital purpura, but these does not occur in more than one-third of all cases [19, 47].

5 Evaluation and Work-Up Including Risk Stratification

Recently updated diagnostic criteria for the diagnosis of PCN are given in Table 1 [11]. Hence, for the diagnosis and classification of the PCN, each patient must be evaluated for the laboratory and radiological factors.

5.1 Initial Work-Up

The initial work-up for patients suspected of having a plasma cell dyscrasia should include:

- Complete blood count with differential count and platelet count
- Serum protein electrophoresis and immunofixation to quantitate and define protein type
- A routine serum chemistry panel (to include calcium, blood urea nitrogen, creatinine)
- Bone marrow aspirate with flow cytometric immunophenotyping and BM biopsy to assess clonal plasmacytosis
- Serum beta-2-microglobulin
- Serum albumin and globulin levels
- Serum free light chain assay
- 24-Hour urine protein, electrophoresis, and immunofixation
- Quantitative serum immunoglobulin levels
- Low dose whole body computerized tomography scan, PET-CT, MRI or Skeletal survey (bone scans contribute little since isotope uptake is often low in purely lytic bone disease)
- Cytogenetics, including FISH (fluorescence in situ hybridization) on bone marrow plasma cells

5.2 Additional Work-Up

Useful data may be obtained by analysis of

- Plasma cell labeling index (PCLI)
- Ploidy analysis
- Immunophenotyping using flow cytometry in bone marrow
- Circulating plasma cells (CPC) using flow cytometry or immunofluorescence
- Lactate dehydrogenase (LDH) levels
- Minimal residual disease (MRD) monitoring

The therapeutic response and clinical outcome in MM patients are significantly heterogenous to the given treatment. This heterogenicity in the overall clinical outcome is alike any malignancy dependent on many factors that include host factors, tumor burden (stage), tumor genetics (cytogenetic abnormalities). Traditionally, tumor burden in MM has been assessed using the International Staging System (ISS) [48] and the Durie Salmon Staging (DSS) [49]. Recently, International Myeloma Working Group (IMWG) has revised the ISS and incorporated the cytogenetic abnormalities (R-ISS) (refer to Table 2) [50]. After the diagnosis of MM

Table 2 Revised International Staging System for MM [50]

Stage	Criteria
Stage-I	ISS-I (serum albumin >3.5, and serum beta-2-microglobulin <3.5) No high-risk cytogenetics Normal LDH
Stage-II	Neither stage I or III
Stage-III	ISS stage III (serum beta-2-microglobulin >5.5) High-risk cytogenetics [t(4;14), t(14;16), or del(17p)] or Elevated LDH

LDH lactate dehydrogenase, *ISS* International Staging System

Table 3 Risk factors associated with multiple myeloma

Risk factors		Prognosis	References
Cytogenetics	Trisomies, t(11;14), t(6;14)	Good	[51, 52]
	t(4;14), gain(1q)	Intermediate	
	t(14:16), t(14;20), del(17p)	Poor	
Flow cytometry	MRD negative status	Good	[7, 53–59]
	Higher number of circulating plasma cell numbers	Poor	[60–62]
	>5% normal PC cells in BM	Good	[63]
	MGUS-like immunophenotypic signature	Good	[64]
	CD81 expression (>25%)	Poor	[65–68]
	CD117 expression (>50%)	Good	[67, 68]
	High plasma cell proliferative rate (PCLI)	Poor	[68]
Molecular	High-risk gene expression signatures (GEP70 and HOVON, among others)	Poor	[7, 16, 51, 69–72]
	TP53 mutations	Poor	
Other factors	Extramedullary disease	Poor	
	Renal failure	Poor	
	Poor performance status	Poor	
	Immunoparesis	Poor	
	Plasmablastic morphology	Poor	

patients are evaluated for the risk stratification and to determine additional prognostic factors that include biochemical, morphological, immunophenotypic, cytogenetic and molecular factors. The list of additional prognostic factors and their value in the management of MM is stated in Table 3. The common radiological features include lytic lesions, pathologic fractures, compression fracture, and osteoporosis.

6 Minimal Residual Disease (MRD) Monitoring

Several recent studies have established the major role of MRD status in the response assessment and prognostication in MM treated with autologous stem cell transplant (ASCT) [54, 55, 57–59, 73–82]. MRD negative status has been highly correlated with progression-free survival (PFS) and overall survival (OS). In MM, for a long period, MRD evaluation was not perceived because of the inability to achieve complete response (CR) with available treatments. However, newer treatment modalities now allow achieving the CR in a large majority of patients, including a significant proportion with stringent immunophenotypic CR [83–87]. Hence, international myeloma working group (IMWG) has included flow cytometric absence of clonal plasma cells in bone marrow as a criterion to define stringent CR (sCR) [57, 59, 74].

MRD can be monitored by either MFC or by molecular techniques. Molecular techniques such as allele-specific oligonucleotide (ASO) PCR, when compared with 3–4 color MFC, have greater sensitivity 23; but time-consuming, labor-intensive, and applicable in a limited number of patients [54, 55, 57, 73, 75, 88–90]. Recent reports on the application of high-throughput sequencing (next-generation sequencing, NGS) appears to be relatively easier but the experience and knowledge of this methodology still premature and limited by laborious standardization and bio-informatics [53]. On the other hand, 8–10 color flow cytometry can be equally or more sensitive technique. MFC applies to a greater proportion of the MM patient population, less time-consuming, and provides sensitivity below the cutoff levels considered to be clinically useful [57, 74]. New methods of flow cytometric MRD monitoring using novel approaches is referred as next-generation flow cytometry (NGF) that is shown to be a highly effective way of MRD monitoring in MM [57]. Thus, MRD status and depth of log reduction in MRD levels by MFC have independent clinical relevance in the monitoring of MM patients and to develop the individualized approach in the management of the disease [79].

7 Principles of Management

Plasma cell dyscrasia represents a spectrum of clonal plasma cell disorder ranging from MGUS to multiple myeloma/plasma cell leukemia, each with differing biology, prognosis requiring specific treatment approach. As the impact of early therapy is being explored in clinical trial setting, in clinical practice patients with multiple myeloma defined as per IMWG guidelines are considered for therapy. Plasmacytomas are treated with local therapy and can be cured in majority of patients, while disseminated disease in multiple myeloma patients requires them to be treated with systemic therapy. Multiagent induction therapy using novel agents followed by consolidation and maintenance is recommended in most of the patients as deeper and long lasting remission achieved with such an approach are associated with improved long term outcomes. Besides anti plasma cell therapy, supportive care like bone strengthening agents, renal support, prevention, and prompt treatment of infections is important for optimal outcomes. Despite all these advances, multiple myeloma remains incurable and continuous follow for timely retreatment is important.

8 Medical Management and Monitoring

8.1 Indications for Systemic Therapy

Patients who meet criteria for multiple myeloma as described above are considered for systemic therapy. Although early therapy for patients who do not meet these criteria has been shown to benefit in patients with high-risk smoldering myeloma, this needs further confirmation [91].

8.2 Therapy for Newly Diagnosed Myeloma

The approach depends on patients risk stratification and eligibility for ASCT. Decision on transplant eligibility can be guided by available published literature to determine the risk-benefit assessment and physiological age is considered than the exact chronological age cutoffs. Most of patents selected at our center for ASCT are less than 65 years of age with ECOG performance status of 0–2. ASCT is usually not recommended in presence of severe compromised heart function (NYHA class 3 or 4) and liver cirrhosis. Traditionally, renal dysfunction is not considered a contraindication for transplant but despite reduced dose melphalan conditioning, limited literature available suggests higher associated toxicities and this needs to be factored in the decision making.

8.3 Initial Therapy

ASCT eligible patients are treated with 3–4 cycles of induction regimen followed by stem cell harvest. There is some emerging evidence that ASCT can be deferred until first relapse [92]. Such an approach requires stem cells be harvested and stored for future use in first few months from diagnosis as risk of failure of mobilization at a later time point may preclude this important consolidation strategy. Besides individual patients risk stratification and comorbidities suggesting a particular regimen to be preferentially suitable for individual patient, availability of salvage options, and ASCT needs to be considered in Indian context. Patients ineligible for ASCT or where upfront ASCT is deferred needs consolidation (usually with same as induction regimen) for a total of 8–12 cycles before initiating maintenance therapy.

VRd regimen has been shown to have survival advantage over Rd and represents one of the current preferred regimens for upfront therapy [93]. Alternative Bortezomib-based induction regimens include VTd and VCd. These regimens were used commonly outside USA due to regulatory issues with lenalidomide in European Union and lack of availability of potent salvage regimens in LMICs or in individual patients with renal dysfunction [94]. KRd (Carfilzomib–Lenalidomide-low-dose dexamethasone) has been shown to be active in many single-arm studies and was recommended for high-risk patients, however based on recent data it is not recommended for NDMM [95]. Daratumumab-based induction therapy is associated with better PFS; however, the comparative phase III study comparing it with VRd is awaited. For patients with advanced age, poor performance status or comorbidities, lenalidomide-low dose dexamethasone (Rd) is an active regimen with good tolerance and better outcome and addition of Daratumumab can be considered based on result of MAIA study. Multi-agent-based regimens using anthracyclines and platinum (VTD-PACE, DCEP, etc.) are particularly useful in aggressive disease such as plasma cell leukemia or patients with multiple extra-medullary plasmacytomas [96]. Unless there is need of initial rapid disease control, as a part of combination induction regimen, once a week subcutaneous bortezomib and low-dose dexamethasone (40 mg weekly) is preferred over intravenous/twice weekly bortezomib and high-dose dexamethasone, respectively [97, 98]. In patients with renal dysfunction, Lenalidomide needs be dose modified or avoided. Plasma exchange with aggressive systemic therapy with VTd or VCd may be considered for patients with cast nephropathy and acute renal failure.

8.4 Autologous Stem Cell Transplant (ASCT)

ASCT is associated with deep and long-lasting remission and remains standard of care despite improved outcomes with novel agent-based therapies. It is safe and equally effective in Indian setting and represents important treatment option given the lack of availability of salvage options. Timing of ASCT has been the question of some of the recent large randomized controlled studies, and there is suggestion that ASCT can be delayed till first relapse but cannot be omitted from therapy of myeloma. Given the logistic difficulty with storing stem cells and limited therapeutic options in relapsed setting, ASCT is best done in upfront setting in our patients. Clinical utility of tandem ASCT is diminishing with advent of novel agents, however, probably young high-risk patients may possibly benefit by this approach [100].

8.5 Post ASCT Consolidation/Maintenance

The role of post ASCT consolidation has been recently challenged in the recent era. BMT-CTN 0702 studied the isolated effect of consolidation RVd for 2 cycles and seems to have no added benefit and hence patients should proceed to maintenance after ASCT [99].

8.6 Maintenance Therapy

Maintenance therapy is recommended for patients following ASCT as well as in ineligible patients after 8–12 cycles of initial therapy as it is shown to be associated with survival advantage [101, 102]. Lenalidomide is recommended for most of the myeloma patients except high risk patients who may benefit by addition of bortezomib to lenalidomide for maintenance therapy. Continuous therapy with longer maintenance seems best in term of PFS; however, optimal duration of maintenance therapy is still not known and one must take into account patient's tolerance, long-term side effects for, e.g., secondary malignancy with lenalidomide, depth of remission as assessed by MRD, patient's preference, etc. and an individualized decision whether to stop maintenance need to be made from case to case basis particularly in non-high-risk patients.

8.7 Prognosis with Current Rx

Revised ISS staging system is commonly used to stage and prognosticate myeloma patients. It is good and powerful system to predict outcomes. Five-year predicted overall survival as per this system for R-ISS I, II, and III is 82%, 62%, and 40%, respectively, while PFS for these three groups are 55%, 36%, and 24%, respectively [50]. Outcomes are rapidly improving and physician and patients alike should be aware about time gap required for survival improvements to reflect the current literature.

8.8 Management of Recurrent Disease Including Specific Palliative Measures

Almost every patient with multiple myeloma relapses, with shortening of remission with each subsequent line of therapy [103]. The prognosis of refractory myeloma is grave with PFS and OS less than 6 and 12 months, respectively, with conventional salvage regimens with novel agents and chemotherapy [104]. While choosing salvage regimen many factors needs to be considered for optimal outcomes. These include remission depth and duration, tolerance to first-line therapy, aggressiveness of relapse, current medical condition of patient, and general condition as assessed by ECOG performance status of patient. Also one needs to make a decision whether a given patient is transplant candidate at time of relapse. Usually fit patients who have not had ASCT earlier or had one as a part of frontline therapy with excellent response (e.g., remission typically lasting more than 36 months with maintenance and more than 18–24 months without maintenance. Usually a triplet with two new drugs to which patient is not refractory is used in salvage regimen preferably with CD38 monoclonal antibody. An early use of daratumumab is recommended given the shorter PFS and poor tolerance in later lines. Patient, who relapses after 6–12 months from stopping of initial regimen, may be considered sensitive and retreated with same drugs. Some patients with indolent relapse or frail patients may be treated with doublets. Patients with aggressive relapse may be treated with multiagent chemotherapy regimen-like VTD-PACE, etc. Duration of second-line regimen has not been studied very well and patients achieving a plateau in response may be considered for stopping of therapy on case to case basis. In refractory patients, one may consider drugs like melphalan/doxorubicin/ bendamustine-based regimen, panobinostat with bortezomib, quadruplet regimens of monoclonal antibody on case to case basis. CAR-T and BiTes have been recently approved and represent relapsed myeloma patients and potentially represent a meaningful treatment options whenever feasible.

9 Role of Definitive Radiation Therapy (RT) for Solitary Plasmacytoma

Solitary bone plasmacytomas (SBP) are radiosensitive tumors with excellent long-term local control with RT (79–91%) [105–111]. For SBP the local tumor and potential local microscopic disease require RT treatment. For solitary extramedullary plasmacytomas (SEP), RT is considered curative strategy. Approximately 25% of SEP in the head and neck region will have regional nodal disease on imaging (MRI and PET/CT) [111]. Therefore, prophylactic radiotherapy to uninvolved nodes is controversial, especially SEP's involving Waldeyer's ring. Nodal recurrences are extremely uncommon (~5%) [108, 112, 113]. In the present era, elective nodal RT is not contemplatedunless there is a strong evidence to indicate a very high risk of nodal involvement (very bulky disease or primary lesion is in very close proximity to the nodes).

9.1 RT Dose Consideration for Solitary Plasmacytoma (SP)

There are no established guidelines for optimal radiation dose for SP's. A large multi-institutional study ($n = 258$) did not show a dose–response relationship beyond 30–35 Gy

[106]. However, it is a common practice to use a RT doses of 40–45 Gy [114]. Mendenhall et al. in a retrospective review of 81 patients reported a local control rate of 94% with 40 Gy or above, which compared with 69% for doses <40 Gy [115]. Studies have reported the futility of RT dose escalation (45–60 Gy) and have reported sporadic local failures at the local site even with doses of 50–60 Gy [105, 116]. A large retrospective study from Princess Margaret Hospital reported the lack of dose response relationship above 35 Gy [109] for tumors 5 cm (100% local control for SBP <5 cm). However, tumors >5 cm diameter had a response of only 38%. It was suggested that higher RT doses is required only for bulky tumors 5 cm or more in maximum diameter [109]. There is also some evidence that SEP is optimally controlled with a dose of 40 Gy or more [111, 117, 118].

RT Dose Practices at Tata Memorial Centre for Plasmacytomas

The following dose guidelines are followed (with dose /fraction of 1.8–2 Gy daily fractions)

- Smaller solitary bone plasmacytoma (<5 cm): definitive RT dose of 45 Gy
- Larger solitary bone plasmacytomas with extensive bone destruction (≥5 cm): RT doses of 50–54 Gy
- Solitary extramedullary plasmacytomas: total dose 45–50 Gy

10 Surgery for Multiple Myeloma

Surgical intervention in SPs is not commonly performed. Specific indications include stabilization of spine. Decompressive surgery is indicated in case of neurological compromise or a combination of the preceding situations.

Vertebroplasty is a commonly performed procedure in cases of structural instability due to myeloma. Vertebroplasty should be attempted in limited vertebral involvement and in the absence of spinal cord compression, which is an absolute contraindication for the above procedure.

11 Multiple Myeloma Palliation with Radiation Therapy

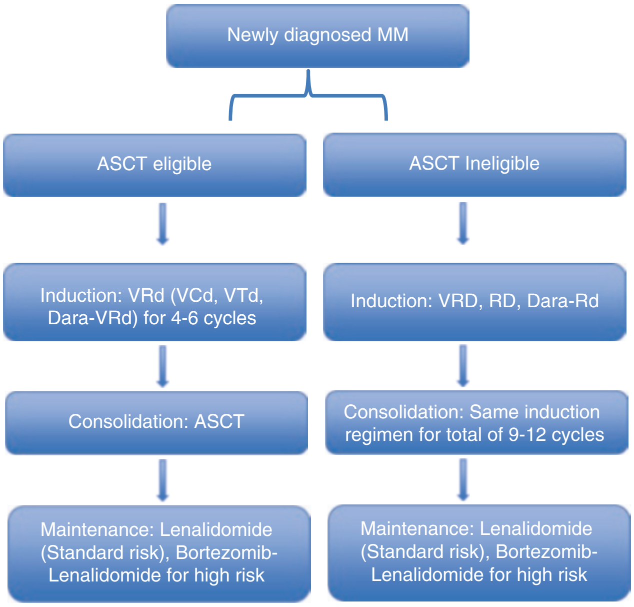
Osteolytic lesions are commonly observed at diagnosis in almost 70–80% of patients with MM [119, 120]. Common presentations include bone pain, pathologic fractures, and neurologic compromise such as spinal cord or nerve root compression, and cranial nerve deficits [121, 122]. RT in MM is for palliation. In case of compression fractures or impending fractures of weight bearing bones, RT should be considered only after surgical intervention as this would not only stabilize the spine/weight bearing bone but also relieve the patient of symptoms due to instability. RT alone has also been shown to be a very effective palliative treatment for patients with spinal cord compression. A retrospective study of 238 myeloma patients has shown excellent response rates (97%), local control (93% at 1 year and 82% at 2 years) and functional outcomes (64% of non-ambulatory patients regained the ability to walk) in patients treated with RT alone [123]. The role of RT in MM is to provide durable pain relief, ameliorate neurologic symptoms, promotes recalcification of bone, and improves quality of life.

In contrast to SP, where doses in the range of 40–54 Gy is required to obtain durable local control (≥85%), lower doses of RT are sufficient to obtain a clinical benefit in patients with symptomatic bony lesions from MM. A retrospective study investigated the most effective radiotherapy schedule in a large cohort of MM patients with spinal cord compression from vertebral body disease [124]. The study compared a short course (8 Gy in 1 fraction; 20 Gy in 5 fractions) to a longer course (30 Gy in 10 fractions, 37.5 Gy in 15 fractions, and 40 Gy in 20 fractions), with respect to improvement of functional outcome for at least 6 months or until death. The long course resulted in higher rates of improvement in motor function, when compared to short course both at 6 (67% vs 43%, $p = 0.043$) and 12 months (76% vs 40%, $p = 0.003$). Conversely, the functional outcomes were similar between the three long course schedules at the given time points. A randomized trial comparing 30 Gy in 10 fractions with 8 Gy in 1 fraction for symptomatic bone lesions in a large cohort of myeloma patients found similar response rates for pain relief but the quality of life improvement with RT was better in fractionated RT arm [125].

RT Dose Practices at Tata Memorial Centre for Palliative RT in Multiple Myeloma

- For bone lesions, where the goal is symptom relief: hypofractionated regimen with total dose of 8–33 Gy (e.g., 8 Gy in 1 fraction, 12 Gy in 2 weekly fractions, 20 Gy in 5 daily fractions, or 33 Gy in 11 daily fractions).
- For epidural disease with spinal cord compression, or a bulky mass, where durable local control is desired, 20 Gy in 5 or 33 Gy in 11 fractions with conformal RT.
- Tapering doses of dexamethasone is recommended for cases with nerve root or spinal cord compression to prevent pain flare (Dexamethasone 4 mg thrice daily to start with and then tapered down slowly).

11.1 Management Algorithm for Multiple Myeloma at TMC (Fig. 4)



Newly diagnosed MM
ASCT eligible
ASCT Ineligible
Induction: VRd (VCd, VTd, Dara-VRd) for 4-6 cycles
Induction: VRD, RD, Dara-Rd
Consolidation: ASCT
Consolidation: Same induction regimen for total of 9-12 cycles
Maintenance: Lenalidomide (Standard risk), Bortezomib-Lenalidomide for high risk
Maintenance: Lenalidomide (Standard risk), Bortezomib-Lenalidomide for high risk

Fig. 4 Management algorithm for multiple myeloma at TMC

Immunodeficiency-Associated Lymphoproliferative Disorders

Anant G. Gokarn and Tanuja Shet

Abbreviations

ALPS	Autoimmune lymphoproliferative syndrome
AT	Ataxia-telangiectasia
BL	Burkitt lymphoma
cART	Combined antiretroviral therapy
CVID	Common variable immunodeficiency
DLBCL	Diffuse large B cell lymphoma
EBV	Epstein-Barr virus
HHV8/KSV	Human Herpes8/Kaposi sarcoma virus
HIgM	Hyper-IgM syndrome
HL	Hodgkin lymphoma
HSCT	Hematopoietic stem cell transplant
IBL	Immunoblastic
KHSV	Kaposi sarcoma associated human herpes virus
LPD	Lymphoproliferative disorder
MACS	Multicenter AIDS Cohort Study
MCD	Multicentric Castleman's disease
NBS	Nijmegen breakage syndrome
NHL	Non-Hodgkin lymphoma
OS	Overall survival
PBL	Plasmablastic lymphomas
PCNSL	Primary central nervous lymphomas
PEL	Primary effusion lymphomas
PID	Primary immune deficiency
PTCL	Peripheral T-cell lymphoma
PTLD	Post-transplant lymphoproliferative disorders
RI	Reduction of immunosuppression
SCID	Severe combined immunodeficiency
SOT	Solid organ transplant
WAS	Wiskott-Aldrich syndrome
XLP	X-linked lymphoproliferative disease

The prevalence of immunodeficiency-associated lymphoproliferative disorders in India is mainly driven by HIV-associated lymphomas. However, with the increasing number of organ transplant centers, the incidence of post-transplant lymphoproliferative disorders is likely to rise.

Immunodeficiency-associated lymphoproliferative disorders (LPDs) are classified into the following broad groups, depending on the underlying immunodeficiency [1]:

- Lymphomas associated with human immunodeficiency virus (HIV) infection
- LPDs associated with primary immune disorders
- Post-transplant lymphoproliferative disorders (PTLD)
- Other iatrogenic immunodeficiency-associated LPDs

1 Lymphomas Associated with HIV Infection

1.1 Prevalence

Lymphoma continues to be a leading cause of cancer-related mortality in HIV patients even in the era of combined antiretroviral therapy (cART). The incidence of lymphoma amongst HIV patients is approximately 2% in the Western world [1, 2]. The estimated burden of HIV-infected patients in India is 2.1 million cases according to UNAIDS 2018 data with an incidence of 0.1 per 1000 population [3]. Non-Hodgkin lymphoma was the most common cancer accounting for 77 of 251 patients with HIV and cancer presenting at the Tata Memorial Hospital (TMH) between 2001 and 2005 [4]. Although there is no large data to confirm the prevalence of

HIV-associated lymphoma in India, it is likely to be a major cause of mortality and morbidity in patients living with HIV and AIDS, as it is globally. In an autopsy study of HIV-positive patients from Mumbai, the incidence of non-Hodgkin lymphomas was 3% [5].

1.2 General Features of HIV-Associated Lymphomas

While Non-Hodgkin lymphomas (NHL) have been labeled as AIDS-defining illnesses since 1985, Hodgkin lymphoma (HL) is not considered an AIDS-defining illness, even though it occurs with increased frequency in HIV patients. Non-Hodgkin lymphoma (NHL) is 60 times more common in AIDS patients than in the general population [6]. Essentially, HIV-associated lymphomas are characterized by a high incidence of extra-nodal presentations, aggressive behavior, and increased association with Epstein-Barr virus (EBV) or Human Herpes8/Kaposi sarcoma virus (HHV8/KSV). Eighty percent of NHLs in AIDS patients are systemic NHL's while primary central nervous lymphomas (PCNSL) form 20% [7, 8]. Of the systemic lymphomas, 40% are diffuse large B cell lymphoma (DLBCL) and 30% each are formed by immunoblastic and Burkitt lymphoma. A drop in the incidence of PCNSL after the availability of cART therapy has been observed. The spectrum of HIV-associated lymphoma varies in different populations. The commonest type of lymphoma seen at our center is diffuse large B cell lymphoma (DLBCL) accounting for 50% and plasmablastic lymphoma accounting for 30% of HIV-associated lymphomas [9]. In a retrospective audit from Tata Memorial Centre conducted between 2000 to 2011, out of 265 HIV-associated lymphomas, 39% were DLBCL (including immunoblastic lymphoma), 45% were plasmablastic lymphomas (PBL), 10% were Burkitt lymphomas, 4% were unclassifiable, 1% was plasmacytoma and 1% had other tumor types (unpublished observations). A distinct absence of HHV8-related lymphomas or lymphoid proliferations was noted in this study which is in sync with the low prevalence of HHV8 in India.

1.3 Pathogenesis

The higher incidence of lymphomas in HIV and AIDS is believed to be due to the following.

- Chronic B cell stimulation and proliferation. It is now clear that the HIV virus is not directly involved in the transformation of B cells [8]. Dendritic histiocytes in the germinal center of lymphoid follicles serve as a sanctuary for HIV virus proliferation leading to chronic B cell stimulation and these stimulated B cells are prone to mutational changes. HIV stimulates monocytes and macrophages to produce IL6 a B cell differentiation factor that functions as an autocrine growth factor.
- Immunosuppression predisposes B cells to a genetic mutation. The nodes that exhibit florid follicular hyperplasia contain clonal B cell populations that are immortalized but not transformed. Lack of adequate immunity due to defective T cell function leads to failure of removal of hyper-stimulated clonal B cells that are genetically unstable and prone to develop translocations, especially in bcl6/cmyc.
- Susceptibility to infection by transforming viruses. EBV/HHV8 infection in HIV patients builds an oncogenic environment. EBV is capable of immortalizing B cells but may be insufficient by itself for tumor development. Likewise, HHV8/KSV is known to activate Cyclin D1 and some cell cycle proteins that can lead to the development of lymphomas indirectly [8].

Three factors determine what type of lymphoma occurs in an HIV-infected person and are also responsible for the heterogeneity of lymphomas in HIV [10]:

- The degree of immune deficiency in the host. The more preserved an immune status of a patient the more differentiated subtypes of lymphomas develop. Thus, Hodgkin lymphoma and diffuse large B cell lymphoma are common in patients on cART and higher CD4 counts while plasmablastic lymphomas occur in patients with severe immune deficiency.
- Coexistent viral infection and molecular pathways affected different ethnic groups. While HHV8 infection gives rise to primary effusion lymphomas (PEL) in severely immunodeficient patients, in populations where HHV8 seroprevalence is low (like India) plasmablastic lymphomas occur more commonly.
- The cell of origin is involved in the development. Depending on the stage at which the B cell development is affected the resultant tumor varies.

1.4 Histologic Classification of Lymphomas Associated with HIV Infection

HIV-associated B cell lymphomas express immunophenotypes similar to those expressed by lymphomas of comparable morphology occurring in immunocompetent individuals. A summary of these lymphomas is presented in Table 1.

1.4.1 Primary CNS Lymphoma (PCNSL) in HIV Patients

PCNSL is uncommon in HIV patients in India and one study quoted 1/56 PCNSL being HIV positive [11]. PCNSL in HIV-positive patients is associated with Epstein-Barr virus

(EBV), whereas EBV is rare in immunocompetent PCNSL patients. Pathologically PCNSL in immunocompetent and immunodeficient patients is similar and shows a centroblastic or large B cell morphology with the characteristic angiocentric pattern. Most PCNSLs (96%) are positive for multiple myeloma antigen 1 (MUM-1) (a marker of germinal center/early post-germinal center B cells), indicating a late germinal center (GC)/early post-germinal center stage of differentiation [12].

Table 1 Histological classification of lymphomas associated with HIV infection

Lymphomas also occurring in immunocompetent patients
• Burkitt lymphoma
• Diffuse large B-cell lymphoma including Primary CNS lymphoma
• Peripheral T-cell lymphoma (rare)
• Classic Hodgkin lymphoma
Lymphomas occurring more specifically in patients who are HIV patients
• Plasmablastic lymphoma
• HHV8 associated B cell lymphoid proliferations and lymphomas
Lymphomas occurring in other immunodeficiency states
• Polymorphic B-cell lymphoma

1.4.2 Diffuse Large B Cell Lymphoma (DLBCL) in HIV Patients

The heterogeneity of DLBCL in non-HIV patients is maintained even in AIDS patients. Amongst the unique morphology, the immunoblastic variant is the hallmark of AIDS-related DLBCL. DLBCLs containing >90% immunoblasts and usually exhibiting plasmacytoid features are classified as the immunoblastic (IBL) variants and 90% of these harbor an EBV infection.

In the AIDS malignancy consortium study, the relative proportion of germinal center DLBCLs was higher than in immunocompetent patients and the frequency of EBV in DLBCLs was not increased in AIDS patients [13]. However, in a study at our institute (unpublished observations) we observed that a third of HIV-associated lymphomas could not be classified as either germinal center or non-germinal center type. Similarly in a study that compared AIDS DLBCL with non-AIDS DLBCL, it was observed that while non-AIDS DLBCL clustered into the germinal center and activated B cell groups easily, AIDS DLBCL did not cluster similarly and showed profiles with overlapping features [14]. Morphologically most HIV-associated DLBL show a dominance of immunoblastic variants and show a high Mib1 index (Fig. 1a, b).

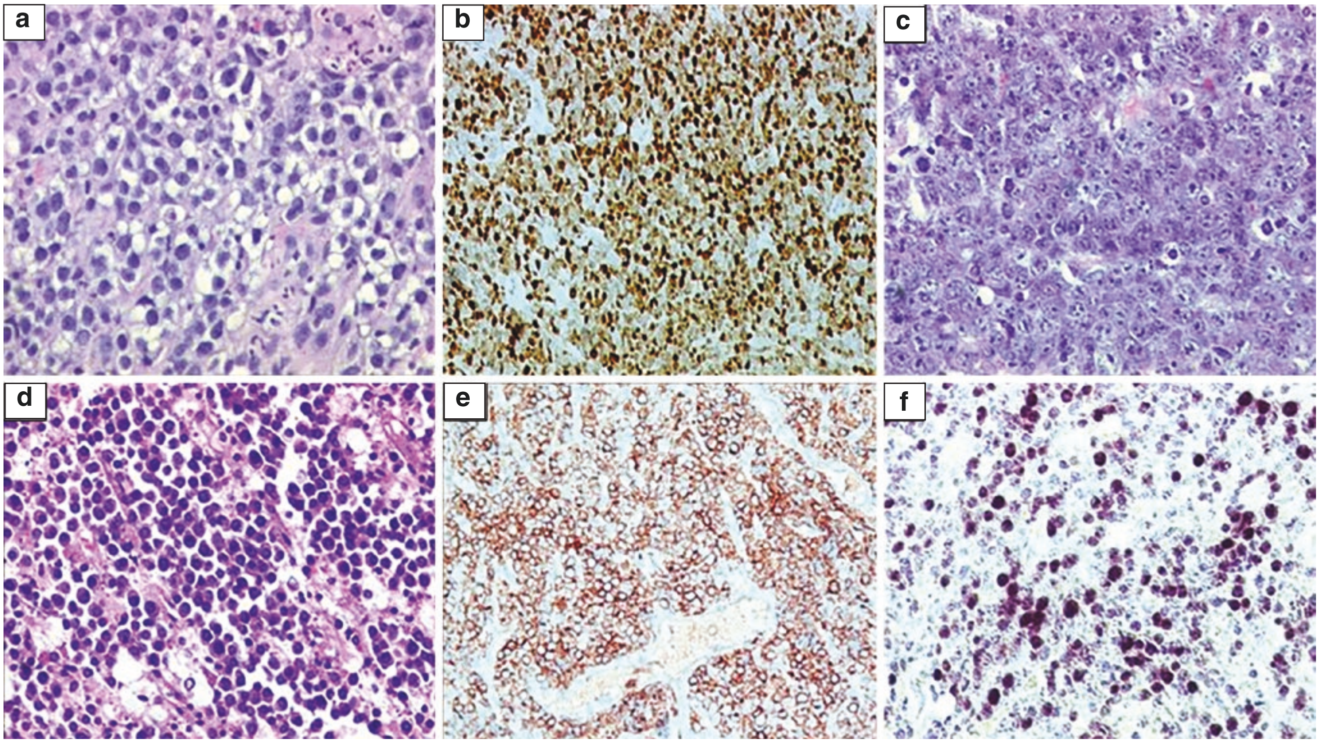

Fig. 1 Morphology of HIV-associated lymphomas. (**a**) Oral large B cell lymphoma with immunoblastic-appearing large cells (H&E 400). (**b**) MUM1 positivity in same (IP 200). (**c**) Plasmablastic lymphoma with blastic morphology (H&E 400). (**d**) Plasmablastic lymphoma myeloma-like (H&E 400). (**e**) CD138 staining in plasmablastic lymphoma (IP 200). (**f**) EBER in situ hybridization shows positive black nuclear staining (ISH 400)

1.4.3 Burkitt Lymphoma

Burkitt lymphoma (BL) is a germinal center tumor with a high proliferation index that needs to be treated with intensive regimens. While BL in immunocompetent patients has extranodal presentation, in HIV patients BL is often nodal in distribution. HIV-positive patients harboring BL are often young, do not usually carry a diagnosis of AIDS, and have fairly preserved CD4 counts [15]. Many AIDS-associated DLBCL show a high proliferative index and often it is not possible to differentiate BL from DLBCL. We have also come across a few Burkitt lymphomas with reduced CD20 expression in HIV patients with low CD4 counts and these pose a diagnostic challenge with plasmablastic lymphomas in these patients.

1.4.4 Polymorphic B Cell Lymphomas

Nador et al. described ten cases of lymphomas in AIDS patients which morphologically resemble polymorphic lymphoproliferation occurring in post-transplant patients [16]. Similar to post-transplant lymphoproliferative disorders PTLD these were characterized by a polymorphous lymphoid cell population exhibiting variable plasmacytic differentiation, cytologic atypia, epithelioid histiocytes, numbers of atypical immunoblasts, and focal coagulative necrosis. None of the patients had a history of severe opportunistic infections or Kaposi's sarcoma or carried a known diagnosis of AIDS at the time of presentation and had low CD4 counts. Improvement of CD4 counts resulted in regression in a few of them.

1.4.5 Plasmablastic Lymphoma (PBL)

This is a highly aggressive B-cell lymphoma with plasmacytic differentiation in HIV-positive patients which commonly affects extranodal sites like the oral cavity, gastrointestinal tract, and lymph nodes [17].

While the clinical spectrum of PBL is well elucidated the pathologic diagnosis has become complex. The vast majority of PBL cases are seen in patients with chronic HIV infection and low CD4 cell counts and cART is of value not only to treat but also to prevent PBL in HIV patients. Given these factors, it is not surprising that this unique lymphoma occurs commonly in Indian patients. Most cases of PBL present with either stage III or stage IV disease. EBV is detected in 74%. PBL is CD20 negative or weak positive; LCA, CD138, CD38, and MUM1 are positive and PAX5 is negative suggestive of post-germinal center immunophenotype. The histological spectrum of DLBCL with plasmablastic features has however widened to include subtypes, such as PBL of oral mucosa type, PBL with plasmacytic differentiation, classic primary effusion lymphoma (PEL), extracavitary/solid PEL or HHV8-associated DLBCL, and ALK-positive DLBCL. There are two histologic subtypes of PBL, one is a blastic type which mimics high-grade B cell lymphomas and the other is myeloma-like which mimics plasma cell neoplasm (Fig. 1c–e). Few DLBL in the HIV setting may show weak CD20 and negativity for PAX5 serves to distinguish PBL from CD20 low DLBL. In our experience, PBL in a non-immunocompromised setting is not common in India and in such cases, a plasmablastic plasmacytoma should be ruled out with a skeletal survey, serum electrophoresis, etc.

More recently, the MYC rearrangement, which is a characteristic of Burkitt's lymphoma (BL), and some DLBCL with very aggressive clinical behavior have been identified as the most common recurrent structural chromosomal alteration in PBL [18].

1.4.6 Primary Effusion Lymphomas (PEL)

Cesarman et al. in 1995 identified Kaposi sarcoma-associated human herpes virus (KHSV) DNA in a unique group of AIDS-associated lymphomas that primarily affected body cavities and presented with effusions [19]. Subsequently, the same team coined the term PEL or primary effusion lymphomas for these tumors. PEL forms 4% of all lymphomas in AIDS patients but has been reported in patients with other forms of immunodeficiency, in non-immunocompromised elderly patients, and in geographic areas with high KHSV prevalence. This subtype is not common in Indian patients just like Kaposi sarcoma, as the seroprevalence of HHV8 in India is low [20].

Microscopically PEL has morphologic features like immunoblastic lymphoma but the PEL cells have enormous size and prominent nucleoli. PEL also share most of their immunophenotype with plasmablastic lymphomas except for association with HHV8, clonal Ig rearrangements, and somatic hypermutations. Hence PEL are LCA positive (95%), showing the absence of B and T antigens, express activation marker CD30, EMA, and plasma cell markers CD138, CD38, and MUM1 with the expression of the KHSV latent protein LNA1. We have encountered intrasinusoidal EBV-associated-PEL-like lymphomas in our patient population (unpublished observation) indicating that PEL may be a morphologic pattern produced by both EBV and HHV8 viruses.

1.4.7 Large B Cell Lymphoma Arising in Multicentric Castleman's Disease (MCD) in HIV Patients

HHV8 is specifically associated with a variant of MCD with lambda light chain restricted KSV positive plasmablasts in the mantle zone of B cell follicles. These plasmablasts in MCD are large with moderate amphophilic cytoplasm and large vesicular nuclei with one or two prominent nucleoli and show CD20, LNA 1, CD138 positivity and light chain restriction but are negative for CD30. Though MCD is known in HIV-positive Indian patients at our institute no HHV8 positivity has been noted (unpublished observations).

1.4.8 Peripheral T Cell Lymphoma

Data on HIV-associated PTCL are largely limited to case reports and small case series. PTCL is associated with low CD4 counts and poor survival. While PTCL-NOS and ALK-negative ALCL morphology are the most common amongst PTCL, the response rate is similar to immunocompetent patients with PTCL and ranges from 50% to 70%. While diagnosing a PTCL in untreated HIV patients with poor immune status pathologists should remember that clonal CD8-positive reactive proliferations that resolve after HAART therapy are known. In our study of NHL in HIV patients most of the atypical T cell proliferations though clonal, turned out to be reactive and reversed after cART therapy and only one pediatric patient died due to CD8-positive T cell lymphoma.

1.4.9 Hodgkin Lymphoma (HL) in HIV Patients

HL represents the most common type of non-AIDS-defining tumor that occurs in the HIV-infected population. After a 12-year follow-up, the Multicenter AIDS Cohort Study (MACS) found the relative risk for HL in HIV-positive individuals versus the US general population to be 7.0. HIV-HL patients have widespread disease at presentation, high incidence of systemic “B” symptoms with frequent involvement of extranodal sites like bone marrow, liver, and spleen, and non-contiguous spread of the tumor. In HIV setting primary marrow Hodgkin’s lymphoma is also known to occur. HL occurring in HIV-infected individuals exhibits pathologic features different from those of HL in the general population including a higher incidence of unfavorable histologic subtypes like mixed cellularity (40–100%) and lymphocyte depleted (20%), and a relatively low prevalence of the nodular sclerosis and lymphocyte predominant subtypes [21]. HL in the HIV setting displays a distinct cellular background, including the presence of a fibrohistiocytoid stromal cell proliferation in the involved lymph nodes. Another morphological characteristic is the abundance of Reed Sternberg cells, mimicking ALCL. A large majority of HIV-related Hodgkin lymphoma (80–100%) are linked pathogenetically to EBV as opposed to HIV-negative HL.

Tables 2 and 3 present the differential diagnosis of CD20-positive and CD20-negative lymphomas in HIV.

1.5 Clinical Features and Approach to Patients with HIV-Associated Lymphomas

Lymphoma may be the first presentation in HIV patients. At our center, lymphoma was the initial manifestation of HIV and led to the detection of HIV at presentation in 21 out of 42 patients (50%) [9]. It is recommended that HIV should be tested in all individuals who present with lymphoma (both Hodgkin and non-Hodgkin). Patients usually present with rapidly increasing mass (nodal or extranodal) along with B symptoms which include fever, weight loss, and night sweats. Oral or facial masses are common presentations, especially

Table 2 Differential diagnosis in CD20-positive AIDS-related lymphomas

Diffuse large B cell germinal center vs. Burkitt		Diffuse large B cell (immunoblastic) vs. plasmablastic	
Large to intermediate-size cells	Intermediate-size cells	Nuclei have a single prominent nucleolus	Nuclei in blastic have a prominent nucleolus
Pleomorphic cells	Monomorphic	Cell cytoplasm pale eosinophilic	Cell cytoplasm plasmacytoid and amphophilic
EBV latency varies	EBV latency I pattern EBER+, occasionallyEBNA1+,LMP1−/EBNA2−	EBER in 30% of tumors Variable latency	EBER in 80% tumors-latency I
Ki67 variable but less likely 100%	Ki67—100%	CD20 variable	CD20 is always focal, never strong positive
Molecular genetics: complex rearrangements including MYC may be seen	Molecular genetics: MYC rearrangements without other rearrangements	IgH gene rearrangements seen	IgH gene rearrangements absent

Table 3 Differential diagnosis of CD20-negative AIDS-related non-Hodgkins lymphomas

Features	Plasmablastic lymphoma	Primary effusion lymphoma	Immunoblastic DLBL
Morphology	Plasmacytoid cells	Immunoblastic or anaplastic cells	Immunoblastic cells
Immunohistochemistry	LCA weak +, CD20 (1–2%), CD138/MUM1 (90%), PAX5 negative EMA (42.5%)	LCA weak +, CD20 (13%), CD138/MUM1 (40%) EMA (70.0%), PAX5 negative	LCA+/−, CD20(+/−), CD138/MUM1+, EMA negative, PAX5 +
EBER-ISH	80% positive	Variably positive	Variably positive
EBV-LMP1	Negative	Negative	Positive
HHV8	Absent	Always present	Absent

of plasmablastic lymphoma in HIV patients. Extranodal involvement of the GI tract, liver, and CNS is more common than in non-HIV patients with lymphoma.

Initial workup should include apart from an HIV test, a CD4 count, and HIV viral load. Renal function, liver function tests, and lactate dehydrogenase (LDH) must also be done. Imaging should ideally include an 18 FDG Positron emission tomography (PET) scan. In case a facility for a PET scan is not available, contrast-enhanced CT scan may be done. CSF cytology to rule out CNS involvement in the case of NHL is mandatory. Tests must also be included to rule out concurrent hepatitis B (HBsAg, core antibody tests, and if required HBV viral load) and hepatitis C infection. Patients must undergo a complete physical examination to look for signs and symptoms of other opportunistic infections such as oropharyngeal candidiasis, tuberculosis other venereal diseases, which may be present simultaneously. An excision biopsy of the lymph nodal mass should be ideally performed. If this is not possible, then a core biopsy or incisional biopsy may be done.

1.6 Treatment

1.6.1 Concurrent cART

Over the last three decades, there has been a significant and dramatic improvement in the overall survival of HIV-associated lymphomas. Apart from better chemotherapy, one of the key factors which have led to this is the use of cART. The use of cART has led to a decrease in the incidence of DLBCL and PCNSL with an increase in the incidence of good prognostic lymphomas such as Hodgkin and Burkitt lymphoma [22]. Although there is no randomized trial comparing chemotherapy with and without cART to establish its effectiveness in HIV-associated lymphomas, there is substantial evidence that cART has improved the survival of HIV patients by improving immunity and decreasing opportunistic infections over the last three decades. Phase 2 data suggest chemotherapy can be combined with cART safely; however, pharmacokinetic interactions especially with cyclophosphamide and drugs such as ritonavir (protease inhibitor) [23]. Also, zidovudine needs to be avoided in view of potential cytopenias when combined with chemotherapy. However, it is not absolutely essential to start or continue cART when giving chemotherapy. Few studies using infusional EPOCH regimens have shown complete remission rates of more than 70% without the use of concomitant cART [24, 25].

1.6.2 Combination Chemotherapy

The presentation of HIV-associated lymphoma may vary from a severely immunocompromised individual to a fit individual with lymphoma. Therapy with curative intent is indicated in all patients with HIV and lymphoid malignancies including in patients with poor performance status as this may be due to malignancy per se or due to opportunistic infections which may improve with supportive care.

1.7 Treatment of DLBCL

Combination chemotherapy with a standard CHOP regimen has been the standard of care for DLBCL in non-HIV settings and has also been used in HIV-positive patients. A randomized trial comparing R CHOP and CHOP in a population of 150 patients with HIV lymphomas (80% of whom had DLBCL, 8% had BL and 4% had other NHL) showed an increase in infection-related mortality in the R CHOP arm (14% vs. 2% in CHOP arm) although the CR rates were much higher in R CHOP arm. However, this increased mortality was mainly seen in those patients who had a CD4 of less than 50 cells/mm^3 [26]. Subsequent phase II studies combining Rituximab with CHOP in HIV positive population showed complete remission (CR) rates of 77% and 2 year overall survival (OS) rates of 75%. These studies included patients with CD4 counts of more than 100 and those mainly with DLBCL, Burkitt lymphoma, and very few patients with plasmablastic and immunoblastic lymphoma. Antiretroviral therapy was also used concurrently. There was no increase in infection-related deaths in this study confirming that R may be safely combined with chemotherapy in patients who have a CD4 >100 [27]. Multiple subsequent trials have safely combined R with chemotherapy regimens in HIV-positive patients.

Infusional dose-escalated EPOCH regimens with or without rituximab have also shown excellent response rates in HIV-positive populations with non-Hodgkin lymphoma [24, 28]. Other regimens such as R CDE also have shown response rates of 70% [29].

Dunleavy and colleagues have further shown that reduction in a number of cycles of EPOCH is possible in combination with dose-dense rituximab (EPOCH RR) without compromising the efficacy of the regimen. In this study, Rituximab was given on day 1 and day 5 along with the 96-h infusional EPOCH regimen in each cycle. A minimum of 3 and maximum 6 cycles were given. A PET scan was done after the second cycle and if not in complete remission was done after each subsequent cycle. Chemotherapy was continued up to 1 cycle beyond the achievement of complete response. The number of EPOCH cycles could be reduced to 3 in 79% of the patients with a progression-free survival rate of >80% at 5 years [25].

Although there are multiple regimens that can be used in HIV-associated DLBCL these are not compared in randomized controlled trials. These regimens use different drugs and different dosing schedules. Few of these regimens have omitted concurrent use of cART and hence their outcomes cannot be compared. However, a meta-analysis using pooled data

Table 4 Summary of different regimens used in treating HIV-associated NHL

Regimen used	Histology included (%)	Median CD4 at baseline (cells/mm^3)	Concomitant use of cART (yes/no)	Complete response rates	Progression-free survival rate	Overall survival rate	Reference
R CHOP (phase II)	DLBCL (70%) IBL (3%) BL (26%) PBL (1%)	172	Yes	76%	69% at 2 years	75% at 2 years	Boué et al. [27]
DA EPOCH	DLBCL (79%) BL (18%)	198	No (deferred till completion of chemotherapy)	74%	73% at 4 years	60% at 4 years	Little et al. [24]
R DA EPOCH (concurrent arm)	DLBCL (79%) BL (21%)	190	Yes, however at the physicians discretion	73%	66% at 2 years	70% at 2 years	Sparano et al. [28]
EPOCH RR (short course)	DLBCL (100%)	208	No	91%	68% at 5 years	84% at 5 years	Dunleavy et al. [25]
EPOCH RR (short course)	BL (100%)	322	No	100%	95% at 6 years	100% at 6 years	Dunleavy et al. [30]

DLBCL diffuse large B cell lymphoma, *BL* Burkitt lymphoma, *PBL* plasmablastic lymphoma, *IBL* immunoblastic lymphoma

from 19 trials with 1546 patients has shown that infusional regimens (EPOCH) led to significant improvement of OS. This study also showed that the use of concurrent cART led to significantly improved CR rates with a trend of improvement in OS [30].

Infusional regimens may be a better choice of therapy whenever feasible-keeping in mind that these regimens are cost-intensive and need substantial supportive care which may preclude their use in resource-limited settings in our country.

Table 4 compares the different regimens used in treating HIV-associated NHL.

1.8 Treatment of Burkitt Lymphoma

Most trials of HIV-associated lymphomas include mainly patients with DLBCL because it is the most common histology and has relatively fewer patients with BL. Chemotherapy with a CHOP regimen in HIV patients with BL has led to poor outcomes. Dose-escalated EPOCH regimens have shown improved outcomes with CR rates of 70% [28]. The use of dose-dense rituximab (EPOCH RR) in patients with BL has also shown a OS rate of 92% at a median follow-up of 73 months in a small cohort of 13 immunocompromised patients [31].

1.9 Treatment of Hodgkin Lymphoma

The treatment outcomes of HL in HIV-positive patients are comparable to those with HL in general. Patients with HIV tend to have more B symptoms, extranodal presentations, and advanced stage. The standard treatment for HIV-associated HL is using an ABVD regimen. The data on the use of ABVD regimens in HIV-positive patients is limited to small studies with few patient numbers. The largest study is from Spain, which included 62 patients of HIV with Hodgkin lymphoma. In this retrospective study conducted between 1995 and 2006, patients received 6–8 cycles of standard ABVD along with cART and growth factors. All patients had advanced disease (Stage III/IV). Five-year OS probability was 76% after a median of 47 months of follow-up [32].

Risk-adapted therapy has also been studied prospectively in a cohort of 108 patients. Patients of early favorable HL receiving 4 cycles of ABVD and 30 Gy involved field radiation (IFRT). Those with early unfavorable HL received either 4 cycles of ABVD and IFRT or 4 cycles of BEACOPP and those with advanced disease received 6–8 cycles of BEACOPP. All patients with advanced HIV disease (CD4 <50, poor performance status, and AIDS-related opportunistic infections) received ABVD only. The CR rates for those with early favorable, early unfavorable, and advanced-stage HL were 96%, 100%, and 86%, respectively. The two-year OS rate was 90.7% in the entire cohort and 95.7%, 100%, and 86.6% in early favorable, early unfavorable and advanced-stage HL respectively [33].

However, there were 7% treatment-related mortality and a higher incidence of grade 3–4 hematologic toxicities in advanced-stage disease, indicating that careful selection of patients is required before planning BEACOPP in HIV-associated HL.

1.10 Treatment of Other Lymphomas

Plasmablastic lymphoma is seen in patients with advanced HIV disease and usually has poor performance status. The data for the management of patients with plasmablastic lymphoma is limited. The outcomes of PBL are poor with CHOP-based therapy. Infusional regimens with DA EPOCH have shown slightly better outcomes. However median survival is still around 9 to 10 months [34]. Primary CNS lymphoma is almost always seen in patients with CD4 <50/mm^3. It is an EBV-associated malignancy and carries an extremely poor prognosis. The optimal treatment is not known. They should be enrolled in clinical trials as far as possible. Radiation therapy to the brain with a focal boost may be used. The use of cART has improved the outcomes in both of these malignancies and must be started upfront for these patients.

1.11 Supportive Care in HIV-Associated Lymphomas

Apart from chemotherapy and cART, another reason for the improvement in survival in patients with HIV-associated lymphomas is the overall improvement in supportive care. The use of prophylactic cotrimoxazole for preventing Pneumocystis Jiroveci infection and azithromycin weekly for Mycobacterium avium infection have led to a decrease in mortality due to these infections. It is important to look for and treat these opportunistic infections at the time of diagnosis and these should be managed simultaneously with the lymphoma treatment.

1.12 CNS Prophylaxis

HIV-associated NHLs have significant involvement in extranodal sites and are at a high risk for CNS disease at presentation and relapse [25]. All patients should receive intrathecal methotrexate with or without cytarabine. Usually, intrathecal injections are given twice weekly till 2 weeks after clearance of CSF followed by weekly for 6 weeks and then monthly for 6 months [25, 31].

2 LPDS Associated with Primary Immune Disorders

Primary immune disorders (PID) are a heterogeneous group of inherited disorders associated with defective immunity rendering a patient susceptible to different viral infections and malignancies. These usually present in the pediatric age group with the exception of common variable immunodeficiency (CVID) which may present in adolescents or young adults.

2.1 Prevalence

The age-specific mortality due to cancer in patients of PID is 10–200 times the general population; however, as PIDs are very rare disorders, they account for only 2% of pediatric lymphomas [35]. The prevalence of primary immune deficiency (PID) in India is statistically estimated to be around 1 million. However, the exact incidence of LPD associated with primary immune disorders is not known. This is due to a lack of diagnostic modalities and awareness [36].

PIDs most commonly associated with LPDs include ataxia-telangiectasia (AT), common variable immunodeficiency (CVID), severe combined immunodeficiency (SCID), Wiskott-Aldrich syndrome (WAS), X-linked lymphoproliferative disease (XLP), Nijmegen breakage syndrome (NBS), hyper-IgM syndrome (HIgM), and autoimmune lymphoproliferative syndrome (ALPS).

2.2 Pathogenesis

PIDs are all associated with poor T-cell function which is responsible for EBV viral proliferation.

Following primary infection, EBV is incorporated in the DNA of the host where it undergoes replication and transformation, especially in circulating B cells. The virus remains in a state of latency and its expansion is controlled by specific cytotoxic T cells. Inhibition of T cell function in these patients due to the PID promotes the proliferation of EBV which expresses BCRF 1 and 2 which helps these cells escape immune control. There is also an increase in the expression of LMP1 and 2 proteins which leads to cell proliferation and escape from apoptosis [1].

2.3 Clinical Features and Management

Most patients have a diagnosis of PID established due to other presenting features and due to recurrent infections in childhood. However lymphoproliferative disorders may be the initial presenting feature in ALPS and XLP. The morphology and immunophenotypes of the lymphomas associated with PID do not differ from those seen in the immunocompetent counterpart. DLBCL is the most common type of lymphoma seen in PIDs in general [37]. Classic HL, BL, and peripheral T-cell lymphoma (PTCL) can also occur. In some disorders like AT and NBS, T-cell lymphomas are more commonly seen than B-cell lymphomas.

Management of these children with PID-induced lymphomas is difficult and the treatments have to be individualized keeping in mind the nature of immunodeficiency and the presence of opportunistic infections which may be worsened by intensive chemotherapy. Allogenic stem cell transplant has been used to treat some of these patients successfully especially those with WAS, SCID, WAS, and HlgM [38, 39].

3 Post-transplant Lymphoproliferative Disorders (PTLD)

These lymphoproliferative disorders specifically occur post solid organ or hematopoietic stem cell transplant. The cumulative incidence of PTLD is low (0.2–1.1%) and mainly consists of B cell proliferative disorders. PTLD has been rarely reported in India, however with an increasing number of organ transplant centers and an increasing number of organ transplants being performed, it is likely to rise.

3.1 Classification

PTLDs are a group of heterogeneous disorders. The current histologic classification of PTLDs is as follows and depends on histology, presence of EBV, and clonality [1]:

1. Non-destructive PTLDs
    (a) Plasmacytic hyperplasia
    (b) Infectious mononucleosis
    (c) Florid follicular hyperplasia
2. Polymorphic PTLD
3. Monomorphic PTLDs (classified according to the lymphoma they resemble)
    (a) B-cell neoplasms: Diffuse large B-cell lymphoma, Burkitt lymphoma, plasma cell myeloma, plasmacytoma, and others
    (b) T-cell neoplasms: Peripheral T-cell lymphoma NOS, hepatosplenic T-cell lymphoma, and others
4. Classic Hodgkin lymphoma PTLD

3.2 Etiology

PTLD is associated with EBV infection, and similar to the pathogenesis of PID-induced lymphomas they occur due to deficient immunosurveillance and proliferation of EBV. EBV induces monoclonal and infrequently polyclonal B-cell or monoclonal T-cell.

3.3 Incidence

In post-hematopoietic stem cell transplant (HSCT), EBV proliferation and PTLD usually occur early within 1 year of transplant and the incidence of PTLD at 10 years is 1–2% [40]. The incidence post-solid organ transplant (SOT) varies according to the organ—it is highest after heart and lung transplant (6%) and is lower after other SOT (1–2% after kidney and liver transplants). The incidence is also significantly higher in children as compared to adults [41].

3.4 Clinical Features

These usually present with the involvement of lymph nodes. Extranodal involvement of the lungs, liver, skin, and GI tract is also common, and almost any site of the body may be involved. CNS involvement is uncommon. PTLD involving allograft has also been described post solid organ transplant and usually occurs in early onset PTLDs and is most common post lung transplants. Tonsillar involvement may be seen in non-destructive PTLDs. Widespread involvement in multiple organs and lymph nodes may be seen post HSCT.

3.5 Prognostic Factors

PTLDs carry a high mortality rate of 50% [42]. This has improved with newer modalities of treatment such as rituximab and EBV-specific T-cell therapy. High LDH, extranodal, multiorgan involvement, bulky disease, and advanced-stage, absence of response to reduction of immunosuppression (RI) are a few of the factors that have been associated with poor survival in some studies.

3.6 Management

Reduction of immunosuppression (RI) is the first and most important intervention that is done in the management of PTLD. Some, especially non-destructive PTLD may regress completely with RI. These lesions carry excellent prognosis, especially in children provided there is no acute or chronic graft rejection that is precipitated by RI. A large proportion of polymorphic PTLD and most monomorphic PTLD would not regress with RI alone and requires further intervention.

Treatment with Rituximab with or without chemotherapy is the standard treatment of PTLD. There is no large data comparing regimens. In a prospective open-label phase 2 trial of 70 post-SOT PTLD patients who had not responded to RI were treated sequentially with weekly rituximab (375 mg/m^2) followed by 4 cycles of 3 weekly CHOP led to median OS of 6 years [43].

In post-HSCT setting monitoring of EBV—especially in high-risk patients (T-cell-depleted transplants, mismatched transplants, and use of ATG) weekly monitoring of EBV viral load and pre-emptive treatment with rituximab before development of lymph nodes or mass lesions has been found to reduce mortality to 0% as compared to 26% in historic controls [44]. Newer modalities like EBV-specific T lymphocyte infusion has shown promising results, however, this is not easily available, especially in developing countries.

Immunodeficiency-associated lymphoproliferative disorders form a significant minority of lymphomas seen in clinical practice. Although prognosis in these disorders is still inferior compared to lymphomas in the general population, interventions like the use of cART, monoclonal antibodies, and infusional combinational chemotherapy regimens have dramatically improved the prognosis and long-term survival.

Histiocytic and Dendritic Cell Neoplasms

Sridhar Epari and Gaurav Narula

Abbreviations

APC	Antigen-presenting cell
BCH	Benign cephalic histiocytosis
BPDCN	Blastic PDC neoplasm
COO	Cell-of-origin
DCs	Dendritic cells
DIDC	Dermal/interstitial dendritic cell
ECD	Erdheim–Chester disease
FDC	Follicular dendritic cells
FDCS	Follicular dendritic cell sarcoma
FRCT	Fibroblastic reticular cell tumor
GEH	Generalized eruptive histiocytosis
HS	Histiocytic sarcoma
IDC	Interdigitating dendritic cell
IDCS	Interdigitating dendritic cell sarcoma
JXG	Disseminated juvenile xanthogranuloma
LC	Langerhans cell
LCH	Langerhans cell histiocytosis
LCS	Langerhans cell sarcoma
MAPK	Mitogen-activated protein kinase
PDC	Plasmacytoid dendritic cells
PNH	Progressive nodular histiocytosis
RDD	Rosai–Dorfman/Rosai–Dorfman–Destombes disease
SHML	Sinus histiocytosis with massive lymphadenopathy
SRH	Solitary reticulohistiocytoma
XG	Xanthogranuloma

1 Introduction

Histiocytic disorders (histiocytoses) are rare lesions, derived from mononuclear phagocytic cells, macrophages and dendritic cells (DCs). DCs, monocytes and macrophages are members of the mononuclear phagocyte system with a distinctive immunophenotypic expression (Table 1), whereas a histiocyte is referred for macrophages in tissue [1].

Table 1 Expression of immunohistochemical markers for histiocyte/macrophage and dendritic cells

Marker	LC	IDC	FDC	PDC	M	DIDC
CD1a	++	–	–	–	–	–
CD4	+	+	+	+	+	+/–
CD21	–	–	++	–	–	–
CD35	–	–	++	–	–	–
CD68	+/–	+/–	–	++	++	+
CD123	–	–	–	++	–	–
CD163	–	–	–	–	++	–
Factor XIIIa	–	–	+/–	–	–/+	++
Fascin	–	++	+/++	–	–/+	+
Langerin	++	–	–	–	–	–
Lysozyme	+/–	–	–	–	+	–
S-100	++	++	+/–	–	+/–	+/–
TCL-1	–	–	–	+	–	–

Abbreviations: *LC* Langerhans cell, *IDC* interdigitating dendritic cell, *FDC* follicular dendritic cell, *PDC* plasmacytoid dendritic cell, *M* macrophage, *DIDC* dermal/interstitial dendritic cell

2 Histiocytes/Macrophages

The histiocytes/macrophages are derived from peripheral blood monocytes and play the role of scavenging of apoptotic cells, necrotic debris and pathogens [2]. They migrate to the tissue and acquire the phagocytic potential in tissue and is one of an integral component of the native innate arm immune system with pro/anti-inflammatory effects, as well as in particulate removal and tissue reconstitution [2]. This phagocytosing macrophages show increased expression of lysosomal enzymes (can be detected histochemically—nonspecific esterases and acid phosphatase stains).

3 Dendritic Cells

Dendritic cells (DCs) play a role in activating naive T-lymphocytes by playing a role in antigen presentation in conjunction with major histocompatibility complex molecules. Based on histogenetic origins, they can be myeloid or stromal derived with different cellular subsets and shows differential immunophenotypic findings (see Table 1) [3].

3.1 Myeloid-Derived DCs

The functional spectrum and activational status of dendritic cells (DCs) or antigen-presenting cells (APCs) is wide and variable depending upon the tissue of its location and its functional role in that tissue. Thus, no single marker identifies all dendritic cell subsets (see Table 1) [4]. Some of the special types are listed below:

- Langerhans cells are specialized DCs, seen in mucosa and skin; where it plays a role of antigen presentation to T-lymphoid cells and subsequently migrate to the regional lymph node through lymphatics. Immunophenotypically, these cells express CD1a and show ultrastructural Birbeck granules (see Table 1).
- Interdigitating dendritic cells: Lymph nodal paracortical dendritic cells, probably derived from the Langerhans cell. This classic dendritic cell lineage is considered to be the cell-of-origin (COO) for Langerhans cell histiocytosis/sarcoma and also of interdigitating dendritic cell sarcoma [5].
- Dermal/interstitial dendritic cells—found in the soft tissue, dermis and most organs, which can be increased in some inflammatory states.
- Plasmacytoid dendritic cells (PDCs) are a distinct type of dendritic cells, currently considered as COO for the blastic PDC neoplasm. Its histogenetic origin is controversial and is classified with the myelomonocytic lineage group [6].

3.2 Stromal-Derived DCs

- Follicular dendritic cells (FDCs) play the role of APCs to B-lymphoid cells within lymphoid follicles (both primary and secondary). They are closely related to bone marrow stromal myofibroblast-like cells. They are nonmigrating and form a stable cell-to-cell meshwork within the germinal center of the follicle [7].
- Fibroblastic reticular cells, on the other hand, ensheath the postcapillary venules and also help in maintaining lymphoid integrity through cytokines. They are also of mesenchymal origin and show myofibroblastic phenotype [8].

4 Spectrum of Histiocytoses

The Working group of the Histiocyte Society, in 2016, categorized histiocytic disorders into five groups based on clinical, radiographical, histological, immunophenotypical, genetic, and/or molecular features (Table 2) [9].

1. L (Langerhans) group—Langerhans cell histiocytosis (LCH), indeterminate cell histiocytosis (ICH), Erdheim–Chester disease (ECD), mixed LCH/ECD.

Table 2 Recent classification of histiocytoses and neoplasms of the macrophage-dendritic cell lineages

Histiocyte Society	WHO classification of tumors of hematopoietic and lymphoid tissues	WHO classification of skin tumors
• **L group** LCH, ICH, ECD, mixed LCH/ECD • **C group (non-LCH of skin and mucosa)** Xanthogranuloma family (includes JXG) Non-xanthogranuloma family (includes MRH) • **M group** HS, LCS, IDCS, IC sarcoma • **R group** RDD (classical and variants) • **H group** HLH (primary and secondary)	• HS • LCH and LCS • IDCT • IDCS • FDCS • DJXG • ECD	• LCH • IDCH/IDCT • RDD • JXG • ECD • MRH

Abbreviations: *DJXG* disseminated juvenile xanthogranuloma, *ECD* Erdheim–Chester disease, *FDCS* follicular dendritic cell sarcoma, *HLH* hemophagocytic lymphohistiocytosis, *HS* histiocytic sarcoma, *IC* indeterminate cell, *ICH* IC histiocytosis, *IDCH/IDCT* indeterminate dendritic cell histiocytosis/tumor, *IDCS* interdigitating dendritic cell sarcoma, *JXG* juvenile xanthogranuloma, *LCH* Langerhans cell histiocytosis, *LCS* Langerhans cell sarcoma, *MRH* multicentric reticulohistiocytosis, *RDD* Rosai–Dorfman–Destombes disease

2. C (Cutaneous) group:
    (a) Cutaneous non-LCH: xanthogranuloma (XG) family (juvenile xanthogranuloma, adult xanthogranuloma, solitary reticulohistiocytoma [SRH], benign cephalic histiocytosis [BCH], generalized eruptive histiocytosis [GEH] and progressive nodular histiocytosis [PNH]); non-XG (cutaneous Rosai–Dorfman disease, NXG, others, NOS).
    (b) Cutaneous non-LCH with a major systemic component.
3. R (Rosai–Dorfman–Destombes) group—sporadic RDD (classical, i.e., nodal; extranodal, neoplasia or immune disease-associated and unclassified) and familial RDD.
4. M (Malignant) group—primary (malignant tumors of histiocytic phenotype, interdigitating, Langerhans, indeterminate cell) and secondary.
5. H (Hemophagocytic) group: primary (inherited conditions), secondary and of unknown/uncertain origin.

5 Histiocytic and Dendritic Cell Neoplasms

Of the above listed histiocytic lesions, the entities that are characterized by clonal molecular abnormalities leading to proliferation of the cells are considered neoplastic. The current 2017 WHO Classification of Tumors of Haematopoietic and Lymphoid Tissues grouped all neoplasms that exhibit stable and constant morphological, phenotypic, and ultrastructural characteristics of terminally differentiated histiocytic and dendritic cells under this category (Tables 2 and 3) [10]. In keeping with this notion, the blastoid plasmacytoid cell neoplasm (as it stems from a cell that acquires terminal differentiation and dendritic appearance following activation) is not considered in this group of histiocytic and dendritic cell and rather is included in the group of acute myeloid leukemia-related neoplasms. Thus, the current 2017 WHO Classification of Tumours of Haematopoietic and Lymphoid Tissues, includes the following entities as histiocytic and dendritic cell neoplasms:

- Histiocytic sarcoma
- Langerhans cell histiocytosis
- Langerhans cell sarcoma
- Indeterminate dendritic cell tumor
- Interdigitating dendritic cell sarcoma, follicular dendritic cell sarcoma, fibroblastic reticular cell tumor
- Disseminated juvenile xanthogranuloma
- Erdheim–Chester disease

RDD was not included under of histiocytic and dendritic cell neoplasms in the 2017 WHO classification of Tumours of Haematopoietic and Lymphoid Tissues, as it was previously perceived to be a nonclonal proliferation. However, recent evidence has shown the clonal nature of at least a subset of cases of RDD, which should be considered as neoplastic and is likely to get updated in the upcoming newer edition of WHO classification. In this chapter, RDD has been listed along with the other above listed entities.

Table 3 Commonly used immunohistochemical markers in the diagnosis of histiocytic and dendritic cell tumors

Antigen	Main reactivity in normal cells	Diagnostic utility
CD1a	LC Dermal DC (subset) IDC (subset)	Required for diagnosis of LCH/LCS and IDCT Positivity excludes IDCS
CD11c	H/M Most DC (most epidermal LC are negative)	Sensitive marker for most H/M and DC neoplasms
CD14	H/M	H/M-derived tumors (less frequent than in monocytic leukemias)
CD68	H/M PDC	Diffuse granular cytoplasmic reactivity in most H/M-derived tumors; variable in DC neoplasms Poor specificity (expressed by many nonhematopoietic tumors, including melanoma)
CD123	PDC Activated macrophages; nodal sinus lining cells high endothelial venule endothelium	High sensitivity and specificity for BPDCN Can be expressed in LCH and in H/M-derived tumors
CD163	H/M	Best markers for H/M--derived tumors (high sensitivity and specificity)
Langerin (CD207)	LC IDC (subset)	Defining LCH/LCS Exclude IDCS
BDCA2/ CD303	PDC	High specificity for BPDCN
Lysozyme	H/M	Often expressed in H/M-derived tumors, but poor specificity
S-100 protein	LC, IDC, activated H/M	Required for of LCH/LCS, IDCT, IDCS and RDD diagnosis Expressed in variable number of cells in various H/M tumors

Abbreviations: *BPDCN* blastic PDC neoplasm, *DC* dendritic cells, *H/M* histiocytes/macrophages, *IDC* interdigitating dendritic cells, *IDCT* indeterminate dendritic cell tumor, *IDCS* interdigitating dendritic cell sarcoma, *LC* Langerhans cells, *LCH* Langerhans cell histiocytosis, *LCS* Langerhans cell sarcoma, *PDC* plasmacytoid dendritic cells, *RDD* Rosai–Dorfman–Destombes disease

6 Histiocytic Sarcoma (HS)

Histiocytic sarcoma (HS) is a malignant tumor of cells with immunohistomorphological features of mature histiocytes (tissue macrophages). However, proliferations associated with monocytic leukemia should not be included in this category. They show mild male preponderance and commonly presents as solitary extranodal mass in adults (median age: 52 years) at sites like soft tissue, skin, gastrointestinal tract and bones, usually associated with systemic symptoms. Rarely can involve lymph nodes and still rarely as disseminated disease (then it should be termed as malignant histiocytosis rather than HS) [11].

Diagnosis is essentially made on histology, which shows relative dyscohesive sheets of large cells of varying shapes with abundant eosinophilic to pale eosinophilic (sometimes with cytoplasmic vacuolation; xanthomatous-like) cytoplasm, significant nuclear atypia and mitoses; in cases of lymph nodes and spleen—usually exhibits sinusoidal growth pattern; erythro/hemophagocytosis by tumor cells can be prominent (Fig. 1). Commonly admixed inflammatory cells—lymphocytes, neutrophils, eosinophils and plasma cells—are noted. Immunohistochemically, the HS cells show positivity of histiocyte/macrophage-associated markers CD163, CD11c, CD14, CD68 and lysozyme. S100-protein is positive in almost 50% of cases and may indicate a co-occurring LC sarcoma component. However, it has to be noted they should be negative for markers of other high-grade hematolymphoid and nonhematolymphoid (mesenchymal sarcomatous) neoplasms.

BRAF mutations (V600E and other variants), activating mutations of RAS/RAF/MEK/ERK, RAS/MAPK and PI3K-AKT-MTOR and loss of the *CDKN2A* gene are frequent genetic alterations [12]. Some cases are shown to be associated with prior or metachronous clonally unrelated low-grade follicular lymphoma, the pathobiology of the same is uncertain.

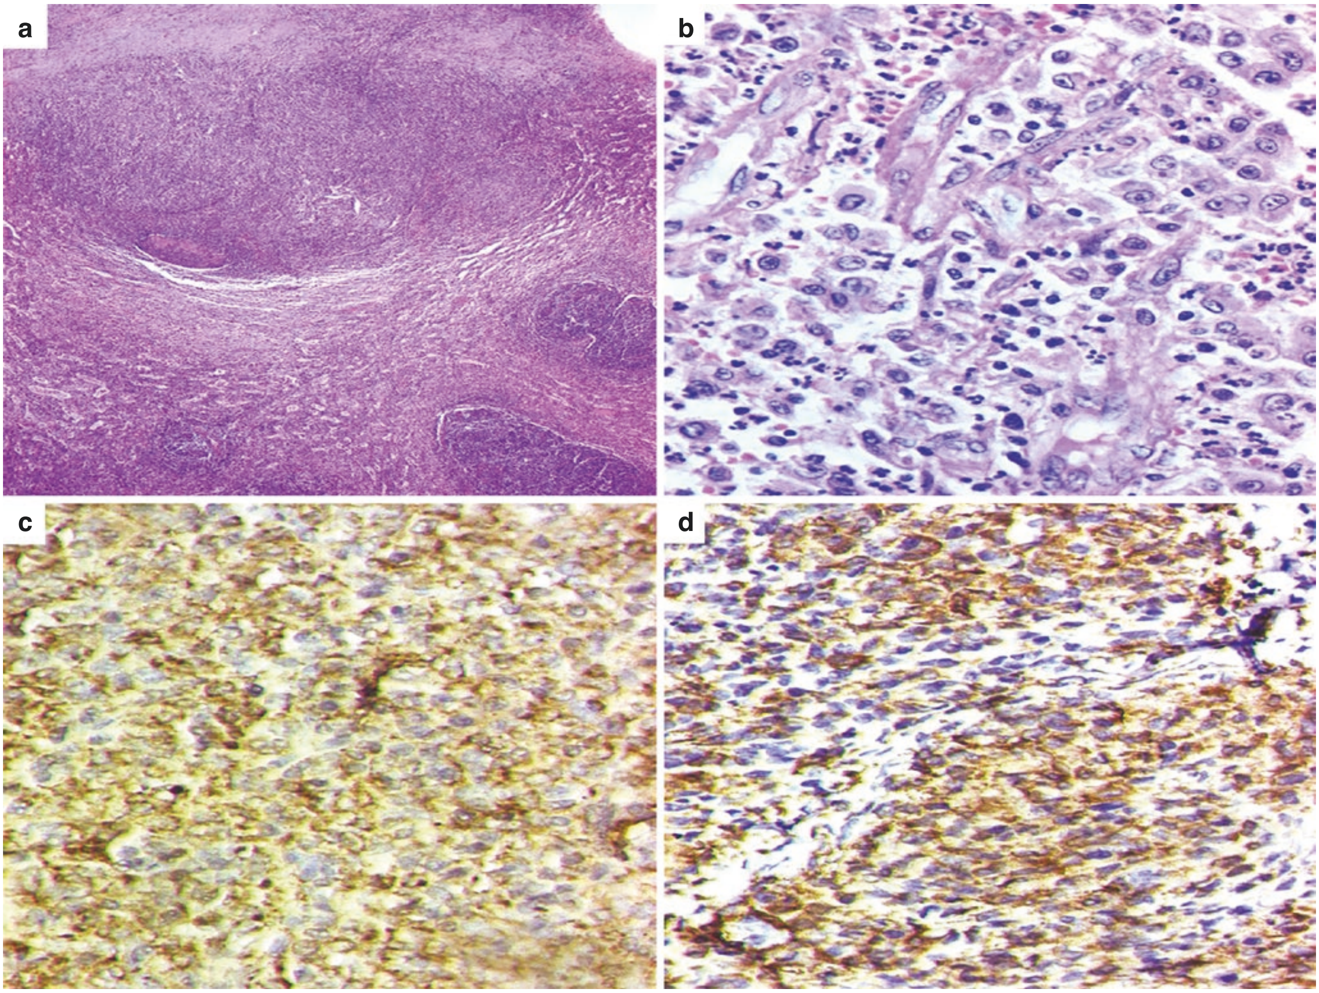

Fig. 1 Representative photomicrographs of splenic histiocytic sarcoma in a 48-year-old male. (**a**) (HE ×40) and (**b**) (HE ×400): Dyscohesive sheets of large cells with abundant eosinophilic cytoplasm with admixed inflammatory cells. The cells show diffuse positivity for CD68 (**c** ×400) and CD163 (**d** ×200)

HSs are aggressive with rare survival beyond 5 years. The localized cased amenable for complete surgical excision however have a better outcome. Currently, no systemic standard treatment recommended, but there are reports of certain degree of responses to *BRAF* and *MAP2K1* inhibitors. Though HS is frequently positive for programmed death ligand 1 (PD-L1) protein, efficacy of anti-PD1 checkpoint therapy is unknown [13].

7 Tumors Derived from Langerhans Cells

Neoplastic proliferation of Langerhans type of cells, which are characterized by immunohistochemical positivity for CD1a, Langerin and S100 protein (see Table 1) and ultrastructural presence of Birbeck granules [10]. These proliferations based on the behavior and degree of aggressive histological features (such as mitotic activity) are classified into Langerhans cell histiocytosis (LCH) and Langerhans cell sarcoma (LCS).

7.1 Langerhans Cell Histiocytosis (LCH)

LCH includes a broad spectrum of clinical manifestations in children and adults, ranging from spontaneously regressive lesions to life-threatening disseminated forms. The diagnosis of LCH is based on clinicoradiological findings along with histomorphological confirmation. It is always advised to do a biopsy for confirmation of suspected LCH lesions.

Historically, LCH was described as three distinct clinical forms: eosinophilic granuloma (≥lytic bone lesions), Hand–Schuller–Christian disease (bone lesions + polyuria + exophthalmos) and Letterer–Siwe disease, a fulminant clinical syndrome (characterized by bone lesions, pancytopenia, hepatosplenomegaly, lymphadenopathy, skin rash, and pancytopenia). The severity of LCH is usually age-related. The current clinical classification of LCH also acknowledges the diverse spectrum, i.e., ranging from localized single-system involvement to disseminated multisystem disease [14]. However, based on the Histiocyte Society working group guidelines, four different groups are defined, depending on the number of organs (or systems) involved, lung involvement and the involvement of one of the three following risk organs (ROs): liver, spleen and bone marrow (i.e., dysfunction of the hematopoietic system) (Table 4) [9].

Table 4 Working group of Histiocyte Society classification of LCH [9]

LCH MS-RO$^-$
Associated with another myeloproliferative/myelodysplastic disorder

Abbreviations: *LCH* Langerhans cell histiocytosis, *MS* multiple system, *RO* risk organ (liver, spleen, bone marrow), *SS* single system

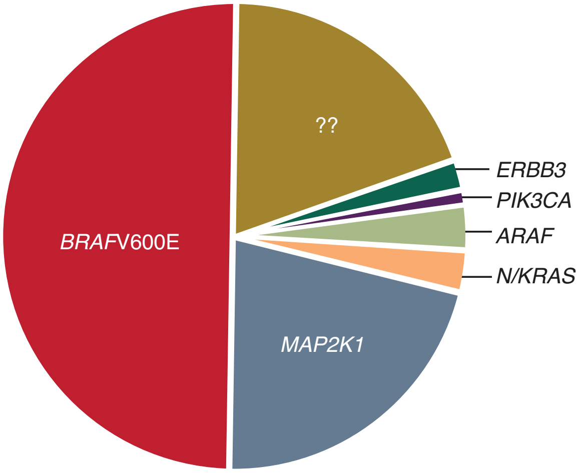

Fig. 2 Pie chart of relative frequencies of activating kinase mutations in LCH (Adapted from [9])

LCH may affect any organ of the body, but bones (80%), skin (33%) and pituitary gland (25%) are the frequent sites in pediatric population. Involvement of liver, spleen, hematopoietic system or lungs is seen in approximately 15%; lymph nodes (5%–10%) and the nonpituitary central nervous system (2%–4%). Lung involvement is more frequent in adults and has been shown an association with smoking. LCH has also been rarely described with other myeloproliferative and T-lymphoblastic neoplasms as phenomenon of transdifferentiation.

Earlier, LCH was considered as dysregulated immune-related disease with abnormal production of cytokines leading to accumulation of LCs with altered cell cycle regulatory mechanisms. However, the identification of clonal alterations, chromosomal instability and telomeric shortening, cell-cycle dysregulation and *BRAFV600E* mutation confirms the neoplastic nature of the disease. Distinct and mutually exclusive activating kinase (ERK) mutations are seen; about 50% of cases show *BRAFV600E* and a fraction of the *BRAF*-wild-type cases show mutations of *MAP2K1, MAP3K1 or ARAF* (Fig. 2). A recent study showed that the mutant allele fraction in LCH was not predictable by tumor cell content and had a significant impact on the efficacy of target therapy. Highly sensitive techniques are therefore recommended in the clinical management of these patients [14–16].

Diagnosis is made from the biopsy from the lesion, which show characteristic histology of atypical large mononuclear cells with coffee bean/kidney-shaped grooved/indented nuclei (sometimes can be lobed) with fine chromatin, inconspicuous nucleoli and thin nuclear membranes admixed with numerous eosinophils, sometimes multinucleated

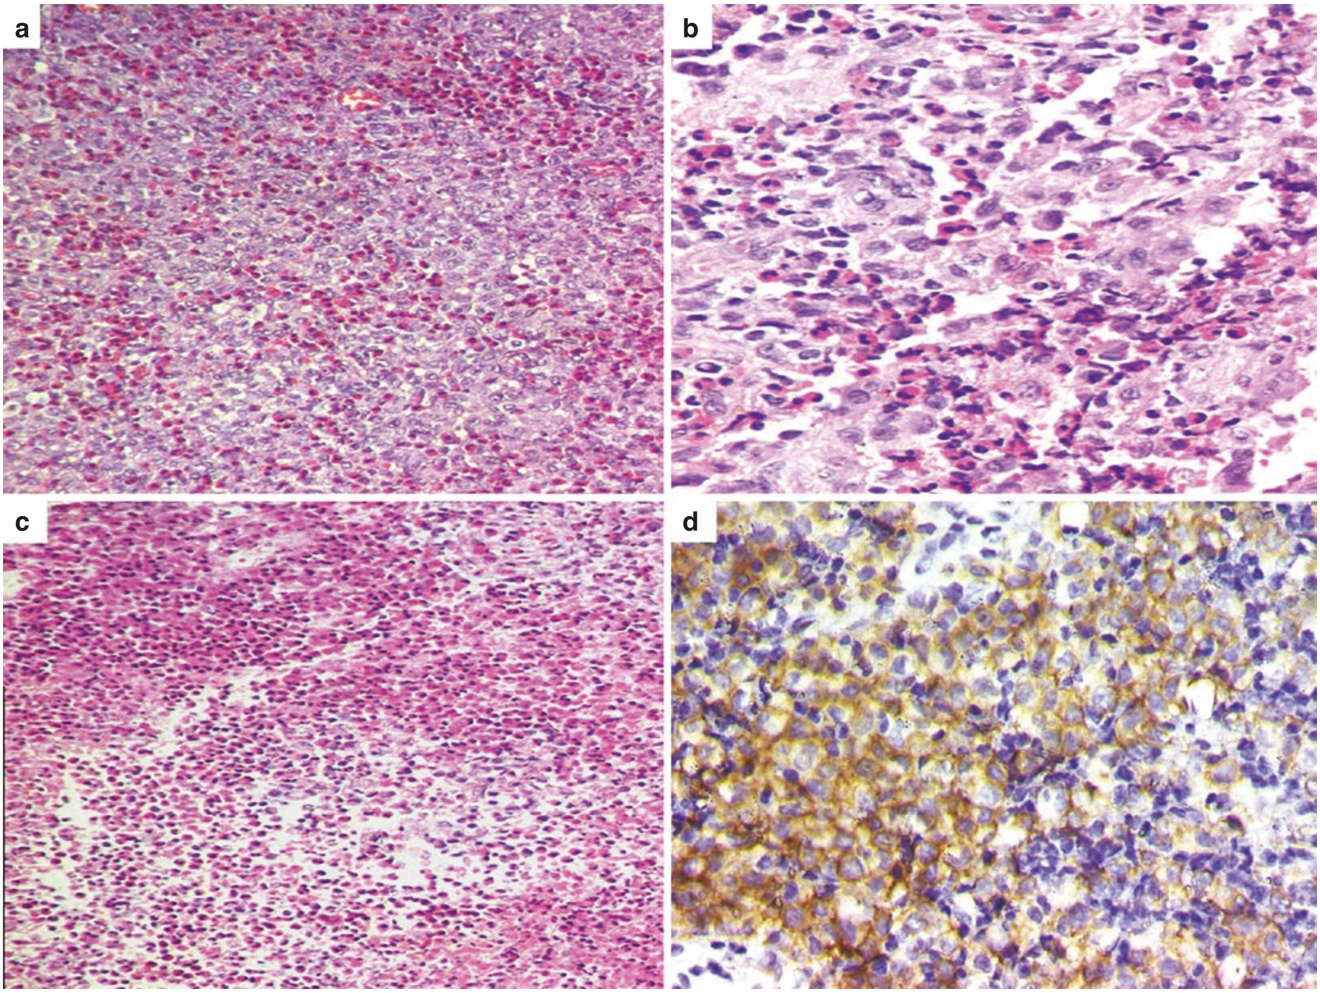

Fig. 3 (**a**) Numerous LCs are seen, with scattered eosinophils. (**b**) Note the typical cytological features of LCs, with many nuclei containing linear grooves. (**c**) Eosinophilic microabscesses. (**d**) The cells show immunopositivity for CD1a

(osteoclast-like) giant cells, neutrophils and small lymphocytes (Fig. 3). Nuclear atypia among the atypical cells is minimal, but mitotic activity is variable and can be high without atypical forms. The cytoplasm is moderately abundant and slightly eosinophilic. Plasma cells are usually sparse. Occasionally, eosinophilic microabscesses with Charcot-Leyden crystals and spotty foci of necrosis can be seen. In early lesions, LCH cells predominate, along with fewer eosinophils and neutrophils. However, with due course of time the percentage of LCH cells decrease; in those instances of late lesions there will be preponderance of foamy macrophages and fibrosis with paucity of LCs. Lymph nodal involvement is usually sinusoidal with secondary infiltration of the parafollicular regions. In spleen, LCH involves the red pulp with nodular pattern sparing the white pulp/periarteriolar lymphoid cell sheath. Liver involvement is usually biliary with sclerosing cholangitis-like pattern. Immunohistochemically, LCH cells are positive for CD1a, Langerin (also called CD207), and S100 protein. In addition, the cells are positive for vimentin, CD68 and HLA-DR. CD45 expression and lysozyme content is low. B-cell and T-cell lineage markers (except for CD4), CD30, and follicular dendritic cell markers are absent. Positivity for PDL1 can also be seen. These features are the same regardless of the extent of the disease.

As a part of standardized clinical work-up, the extent of disease should be assessed in all patients, which can be done by the following tests:

- Complete blood count, serum electrolytes levels and biochemical evaluations, including liver and renal function tests should be done. In cases with hepatomegaly, a coagulation work-up should also be done.
- Urine tests: Routine urinalysis and if indicated (especially to rule out diabetes insipidus), a water-deprivation test also should be done.
- Bone marrow aspirate and biopsy: This should be done in multisystemic cases with anemia and thrombocytopenia.

- Radiologic and imaging evaluation: This is recommended in all cases to categorize as single or multisystemic disease. This should include a whole body skeletal survey and wherever possible with radionuclide scanning especially PET-CT scan.

The clinical course is essentially related to the extent of disease involvement. Extensive multisystemic form is often diagnosed in children ≤5 years with a poor prognosis and mortality rate up to 50%. In infants, even focal disease can sometimes progress to multisystemic involvement. A well-defined unifocal bone restricted disease is primarily a disease of older children and has more than 99% survival probability. Thus, treatment essentially depends on the extent/stage of the disease and is tailored based on the risk stratification [16, 17].

- Low-risk disease (single-system or multisystem):
  - Isolated skin involvement, which has been excised completely, can be observed. In case of residual lesion, can be treated with topical application of steroids with or without psoralen and UV light. However, if no other site is involved, most lesions resolve spontaneously and only observation would be required. Single-site, single lesion disease may not require any intervention.
  - Skull-bone lesions (in the mastoid, temporal, or orbital bones) poses risk for subsequent CNS involvement and thus need to be treated with 6 to 12 months of vinblastine and prednisone. Wherever needed, especially neurological symptoms/defect/instability (in vertebral cases), surgical corrections should be advocated. In cases of vertebral involvement with soft tissue component, chemotherapy is often successful. However, in cases of completely curetted solitary bone lesions, especially in adults may not require any adjuvant therapy.
  - Multifocal involvement (such as multiple bone lesions; or combinations of skin, lymph node, or pituitary gland with or without bone lesions) should be treated with 12 months of vinblastine and prednisone. Bisphosphonates are also effective in extensive bone lesions.
- High-risk multisystemic disease:
  - The standard therapy for high risk organs involvement is combination chemotherapy of vinblastine, prednisone and 6-mercaptopurine for 6 months to 1 year.
  - CNS disease: In case of deficient blood-brain barrier, drugs such as cladribine (2-CdA), or other nucleoside analogs, such as cytarabine, are the best options. In cases with disease-related neurodegenerative features, treatment with drugs like dexamethasone, retinoic acid, intravenous immunoglobulin, infliximab with or without vincristine can be used.

7.2 Langerhans Cell Sarcoma (LCS)

Malignant tumor with overt aggressive histological features and retained immunophenotype of mature LCs [10]. Unlike LCH, LCS is rare and occur in adults, usually affecting skin and soft tissue. Multisystemic forms involving lymph nodes, lung, liver, spleen, and bone are very rare. The clinical features depend on the sites of the involvement and they are similar to LCH. Diagnosis is essentially made on histology, which is characterized by nuclear pleomorphism and a very high mitotic rate (usually >50/10 hpfs). Unlike in LCH, admixture of eosinophils is uncommon in LCS. Immunohistochemical findings are similar to LCH but the expression pattern is more heterogeneous. These patients should be worked up and treated like LCH; however, the prognosis is very bad as compared to LCH [15].

8 Indeterminate Dendritic Cell Tumor

Neoplastic proliferation of cells with immunophenotypic features of normal indeterminate cells, which are thought to be precursors of Langerhans cells (LCs). This tumor is extremely rare and usually presents as multiple/generalized or uncommonly solitary skin nodules, papules or plaques with no systemic symptoms with only rare noncutaneous (lymph node and spleen) presentations [18]. Histologically, the lesions are seen in the dermis with/without involvement of the subcutaneous tissue, composed of histiocytoid cells resembling LCH cells with areas of spindle cell morphology. However, admixed eosinophilic infiltrate is usually not present. Immunohistochemically, the cells are positive for S100 protein and CD1a; while negative for Langerin (CD207), CD163 and dendritic cell markers (CD21, CD23, CD35). Ultrastructurally, they do not show Birbeck granules. *BRAF* and other MAPK-related mutations are rare, while ETV3-NCOA2 gene fusion has been reported in very few cases. Most cases have an indolent clinical evolution, even with spontaneous regression. No prognostic factors are known for these tumors.

9 Interdigitating Dendritic Cell Sarcoma (IDCS)

IDCS are neoplastic proliferation of cells with immunophenotypic features of interdigitating dendritic cells. These are very rare tumors seen in adults usually presenting as isolated enlarged lymph nodal mass with no associated systemic symptoms. Nonnodal, especially skin and soft tissue, involvement has been very rarely reported.

Like the other tumors of this broad group, the diagnosis is essentially histology-based, which shows characteristic paracortical proliferation of ovo-spindloid-shaped cells with fascicular, whorling and storiform architecture. The cells are predominantly mononuclear with variable presence of occasional multinucleated forms. Mitosis is usually low and necrosis is absent. Admixture of small reactive lymphocytes and lesser population of plasma cells are usually seen. Immunohistochemically, the neoplastic cells are positive for S-100 protein, fascin, variably positive for CD68 and CD45. They are negative for CD1a, Langerin, FDC markers (CD23, D21, CD35), CD30, EMA and cytokeratins. Unlike the follicular dendritic cell sarcoma cells, the IDCS cells do not show ultrastructural desmosomes. No specific genetic alterations are reported for this entity. The clinical presentation depends on the site/s of involvement of the diseases. Stage is an important prognostic factor; whereas no clinical correlation was observed for histological features. To date, surgery is the main form of the treatment. They are not shown to be chemosensitive and do not respond to the chemotherapy protocols, especially in cases of nonresectability/incomplete resection, where option of radiation therapy can be considered. The clinical course is usually aggressive with 5-year survival rates of only 50% [11, 19].

10 Follicular Dendritic Cell Sarcoma (FDCS) and Fibroblastic Reticular Cell Tumor (FRCT)

Follicular dendritic cell sarcoma (FDCS) is rare malignant tumor with immunohistochemical phenotype of follicular dendritic cells (FDCs; nonhematopoietic mesenchymal-derived dendritic cells), generally more common in adults. Extranodal presentations are commoner than nodal and are usually not associated with systemic symptoms. About 10% of cases occur in the background of hyaline-vascular type of Castleman disease. Histologically, the neoplastic cells show similar cytomorphological features as that of IDCS but the involvement is usually more diffuse and follicular rather than parafollicular. The tumor can show wide spectrum of histomorphology and thus can mimic different mesenchymal and epithelial neoplasms (Fig. 4). Immunohistochemically, FDCS cells are positive for FDC markers (CD21, CD35, and CD23). Clusterin is often strongly positive (this can serve as good diagnostic differentiating marker from dendritic cell neoplasms as this usually negative or only weakly positive in other dendritic cell tumors). The tumor is variably positive

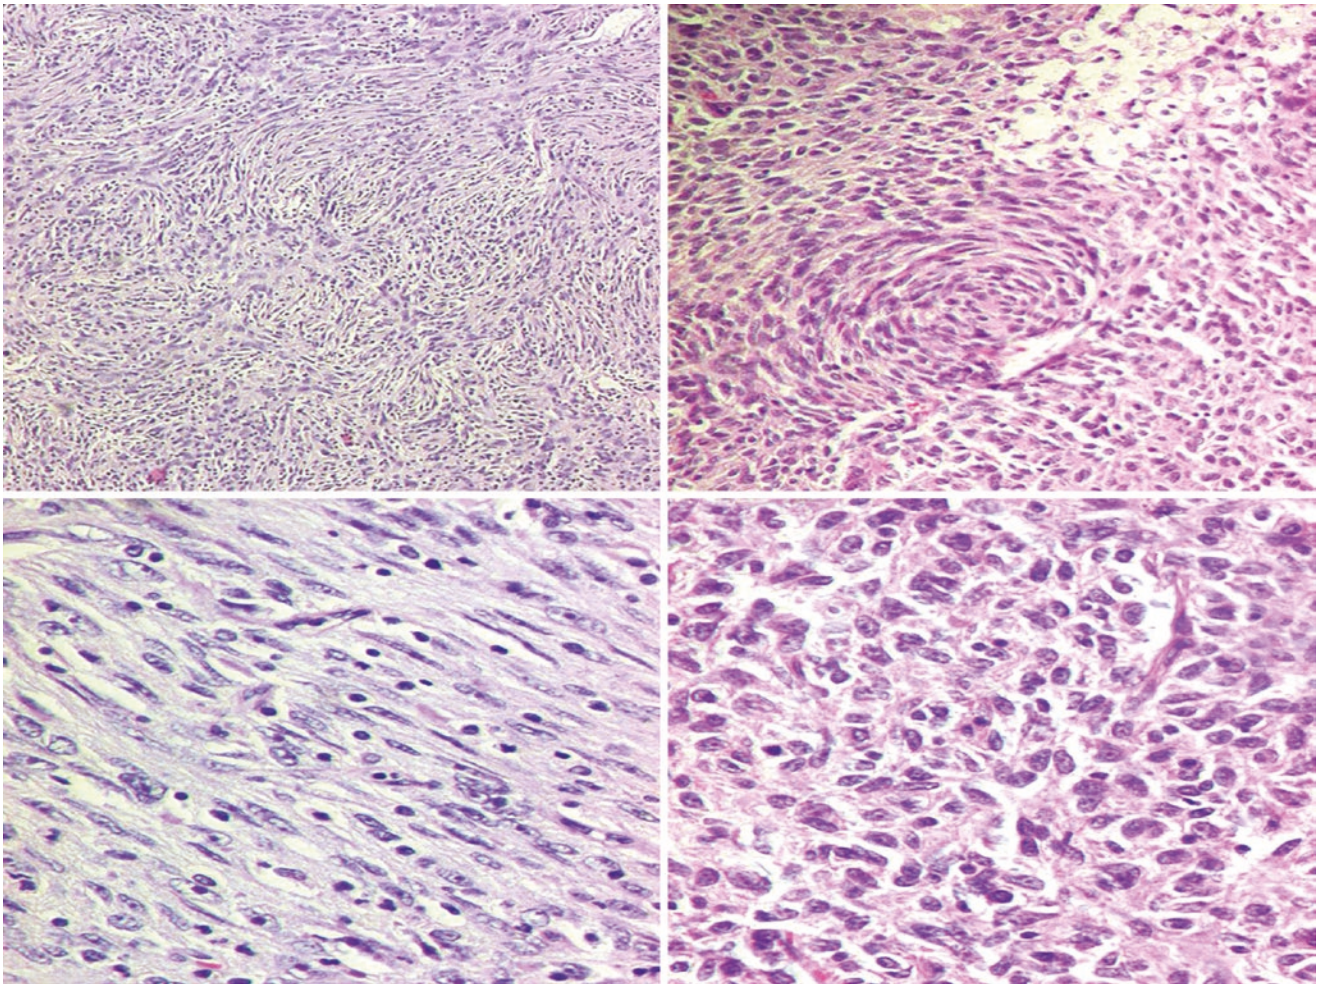

Fig. 4 Follicular dendritic cell sarcoma: histomorphological spectrum

for EMA, S100 protein and CD68; while negative for cytokeratin, Langerin and CD1a. A distinct inflammatory pseudotumor variant (seen predominantly in intra-abdominal locations) shows positivity for EBV. FDCS behavior is variable; the prognosis is excellent in localized surgically excisable cases [20].

FRCTs are also tumors similar to those of IDCS and FDCS but without the immunophenotypic features of IDCS and FDCS. Rather these tumor cells show immunophenotype related to myofibroblast (SMA, desmin and cytokeratin positivity). The clinical and biological basis of these tumor is not much known as they are extremely rare. Thus treatment protocols are similar to that of FDCS and IDCS.

11 Xanthogranulomatous Group of Diseases: Disseminated Juvenile Xanthogranuloma (JXG) and Erdheim Chester Disease

Disseminated juvenile xanthogranuloma (JXG) is characterized by a proliferation of voluminous foamy/xanthomatous histiocytoid cells variably admixed with Touton-type of giant cells with immunophenotypic features of macrophages. They can be solitary or disseminated; the former is more common. Skin and soft tissues are common locations. The disseminated forms usually involve mucosal surfaces of upper aerodigestive tract. No consistent cytogenetic or molecular alterations has been identified. Clinical presentation depends on the sites of involvement—usually related to local mass effect. The CNS forms show LCH-like clinical features; however in liver unlike LCH, JXG do not target biliary system. The clinical course is usually benign (except in CNS, where sometimes the local effects can be catastrophic) but rarely can present with macrophage activation syndromes. Systemic forms that involve liver and bone marrow can been treated like LCH [21].

Erdheim–Chester disease (ECD) is a rare clonal systemic proliferation of cells with similar morphological features of JXG, occurs mostly in adults. It is different from JXG by the presence of the clonal genetic alterations [9]. Majority of patients have multiorgan involvement; commonly involving long bones (>95%), cardiovascular system (50%) and retroperitoneum (30%). Virtually, any organ can be involved in ECD. Osteosclerosis of distal lower limb long bones with pain is a pathognomonic feature. Diagnosis of ECD is essentially based on clinical features, imaging, and histology. Consensus diagnostic criteria for ECD include (1) xanthogranulomatous lesions containing CD68 positive but CD1a-histiocytes, (2) symmetric skeletal uptake of the long bones of the legs on Tc bone scintigraphy, FFDG-PET or MR imaging and (3) involvement of at least one other organ typically affected by the diseases (e.g., xanthelasma, perinephric infiltration, "coated aorta," pericardial infiltration). Molecularly, unlike JXG, ECD shares with LCH of activation ERK signaling pathway in almost all the cases. Almost 95% of cases of ECD show one mutation of the MAPK pathway; BRAFV600E mutation is the commonest (approximately 50%–65%), followed by MAP2K1, ARAF, MAP2K2, NRAS and KRAS. Mutations of PIK3CA have also been reported independent of BRAF status. The clinical course is like a chronic disease and depends on the extent and distribution of the lesions. Though spontaneous regression has been reported, but the disease is usually progressive in untreated patients due to damaging changes on kidneys, the cardiovascular system, lungs and CNS. Like in LCH, CNS involvement is one of the major worse prognostic factors. Treatment with interferon-alpha and targeted BRAF and MEK-inhibitors have been used with good results. However, the duration of the treatment is subject of concern as interruption of treatment has shown to have recurrences [22–24].

12 Rosai–Dorfman Disease/Rosai–Dorfman–Destombes Disease (RDD)/Sinus Histiocytosis with Massive Lymphadenopathy (SHML)

RDD is characterized by proliferation of large, pale histiocytic cells exhibiting emperipolesis, morphologically represented by the intracytoplasmic presence of intact inflammatory cells (usually plasma cells or small lymphocytes). Emperipolesis is an active process of engulfment/penetration of an intact cell into another cell and resides there temporarily without degradation (unlike the process of phagocytosis, which involves degradation and irreversible process). The updated Histiocyte Society classification of histiocytoses categorizes RDD into classical RDD, extranodal RDD, immune-disease-associated RDD, neoplasia-associated RDD and familial RDD (Fig. 5) [9]. Recent molecular studies showed clonal activating kinase mutations involving *KRAS, NRAS, MAPK1* and *ARAF* in a subset, suggesting that RDD represents a neoplastic process at least in some instances. However, unlike in LCH and ECD, *BRAF* mutations are not common in RDD [25].

The classical, i.e., nodal, form usually presents as massive bilateral cervical lymphadenopathy in young individuals. Many (almost up to 40% of cases) show at least one extranodal involvement. Some cases are exclusive extranodal and few can show a systemic involvement. The extranodal sites affected in RDD include nasal cavity and paranasal sinuses, orbital tissue, skin and bones. Central nervous system lesions are very rare are meningeal-based. Patients often present with fever, hyper-gammaglobulinemia, elevated erythrocyte sedimentation and hematological abnormalities. Few cases are shown to be associated with autoimmune diseases like

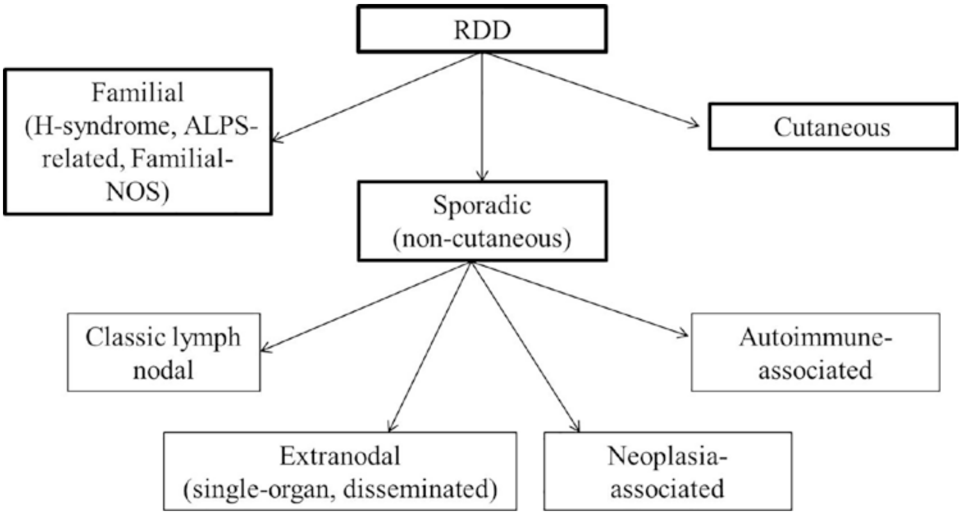

Fig. 5 Schematic classification of RDD as per the updated Histiocyte society working group. *AIHA* autoimmune hemolytic anemia, *ALPS* autoimmune lymphoproliferative syndrome, *ECD* Erdheim–Chester disease, *IJA* idiopathic juvenile arthritis, *LCH* Langerhans cell histiocytosis, *MH* malignant histiocytoses, *NOS* not otherwise specified, *SLE* systemic lupus erythematosus

systemic lupus erythematous, idiopathic juvenile arthritis and autoimmune hemolytic anemia. IgG4+ plasma cells can be elevated, even reaching the cut-off values of IgG4-related diseases; though, the significance of this finding remains unclear, it is now recommended to evaluate for IgG4/IgG ratio is recommended in all RDD cases. The findings of the same should be documented at time of diagnosis [9, 26].

Histologically, the lymph nodes characteristically show dilated sinuses filled by large pale macrophages containing intracytoplasmic variable numbers of undamaged lymphocytes, neutrophils and plasma cells (emperipolesis) (Fig. 6). The rest of the nodal parenchyma shows prominent plasma cell infiltrate. Immunohistochemically, the macrophages are typically positive for S100, CD68 and CD163; while negative for CD1a and Langerin (CD207). Plasma cells are usually polyclonal with a variable fraction of IgG4+ cells. Extranodal RDD shows a relative more heterogeneous morphology of small foci or scattered typical macrophages admixed with dense polymorphic inflammatory infiltrate and fibrosis. The macrophages can be obscured by the inflammatory cell infiltrate and moreover, emperipolesis can be negligible. In these cases, S100 immunopositivity with clinical correlation can be very helpful to identify. The familial cases also show similar histomorphological features as described for sporadic lymph nodal and extranodal cases.

Sporadic RDD has a good outcome; asymptomatic patients with adenopathy and cutaneous disease can be observed. Surgical excision may be indicated in unifocal extranodal disease or for mass-related symptomatic cases. Those with multifocal irresectable extranodal disease may require systemic therapy. Though there is currently no standardized regimen; different systemic therapies for these patients include corticosteroids, sirolimus, chemotherapy, immunomodulatory and radiotherapies. In cases with severe and refractory diseases, targeted next generation sequencing for mitogen-activated protein kinase (MAPK) mutations is advised for institution of potential targeted therapy if any variant identified.

Key Points

- Histiocytic and dendritic cells tumors are rare, and diagnosis is histology-based and requires an appropriate panel of immunohistochemical markers and in some instances, molecular tests and clinical features.
- Histiocytic sarcoma should be considered in all tumors showing large atypical cells with abundant eosinophilic cytoplasm lacking markers of more common high-grade lymphoid and nonlymphoid neoplasms in absence of monocytic leukemias.
- Diagnosis of Langerhans cell histiocytosis is substantially based on the typical histology of coffee bean-shaped grooved nucleated histiocytoid cells admixed with eosinophil-rich inflammatory cells infiltrate and osteoclast-like giant with a typical immunohistochemical expression of CD1a, Langerin/CD207 and S100. Detection of *BRAFV600E* mutation is useful to support diagnosis in doubtful cases. Treatment strategy is stage-based.
- Indeterminate dendritic cell histiocytosis/tumor differs from Langerhans cell histiocytosis by lack of Langerin/CD207 expression.
- Erdheim–Chester disease diagnosis is now separated from Juvenile xanthogranulomas by the presence of genetic alterations (*BRAF, MAP2K1, ARAF, MAP2K2, NRAS and KRAS*); though it may share the clinical, radiological and pathological features.
- Rosai–Dorfman/Rosai–Dorfman–Destombes disease represents a heterogeneous group of disorders all characterized by tissue infiltration by S100 protein positive large macrophages exhibiting emperipolesis. At least a subset of them are clonal, thus neoplastic.

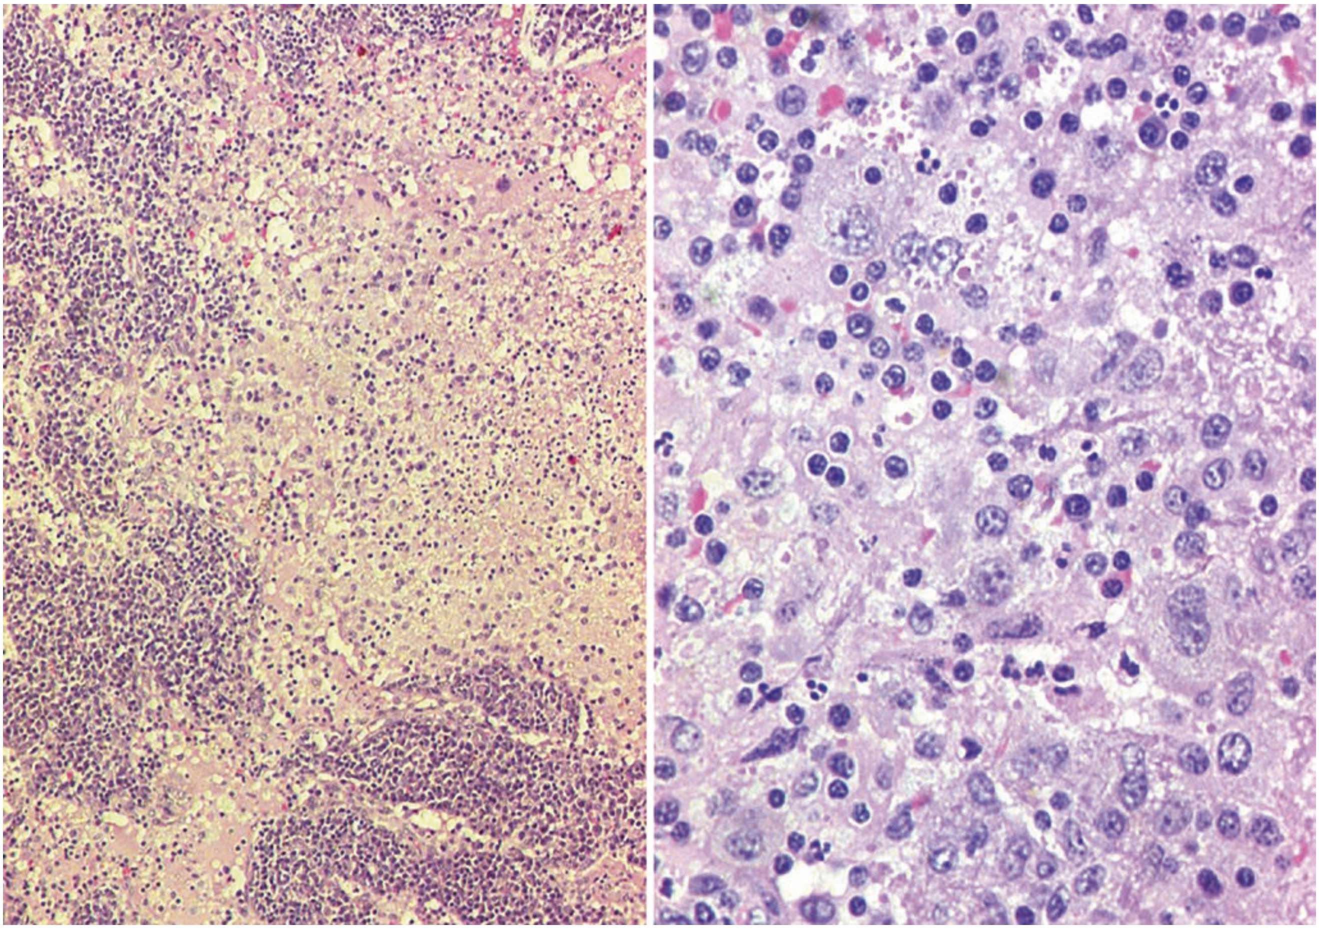

Fig. 6 Nodal Rosai–Dorfman disease, characterized by large pale macrophages with emperipolesis of other inflammatory cells

1 Introduction

The term leukemia ("white blood" from Greek leukos [white] and haima [blood]) was coined by Rudolph Virchow in 1845 for a blood disease with a splenic enlargement [1]. By 1913, four types of leukemia were recognized—chronic lymphocytic and myelogenous leukemias, acute lymphocytic leukemia, and erythroleukemia. Childhood leukemia was, however, not differentiated into lymphoid or myeloid till 1950, and was invariably fatal due to bleeding and/or infection [2]. It is now broadly classified into acute lymphoblastic, myeloid, and mixed phenotypic leukemias—ALL, AML, and MPAL, respectively. Within the AMLs, Acute Promyelocytic leukemia (APML) is considered sufficiently distinct to merit separate attention. For the purpose of this chapter, ALL, AML, and APML are discussed as separate entities.

2 Acute Lymphoblastic Leukemia

2.1 Introduction

The modern therapy for childhood leukemia began with Sidney Farber, a Boston-based pathologist, who first used 4-amino pteroylglutamic acid (aminopterin) an analog of methotrexate (synthesized by Y. Subbarow, a New York-based pharmacologist) to treat 16 children with acute undifferentiated leukemia [3]. Temporary remissions with clinical, hematological, and pathological improvements were recorded in ten children, ushering in the modern age of cancer chemotherapy [4]. During the 1950s and 1960s, new drugs were discovered including the vinca alkaloids, anthracyclines, 6-mercaptopurine (6-MP), and platinum compounds, leading to the first combination chemotherapy trials by Frei and Freireich at the National Cancer Institute (NCI), Pinkel and Holland at Roswell Park Cancer Institute and Burchenal at Memorial Sloan-Kettering Cancer Center [2].

The current 5-year survival rates in childhood ALL have crossed the 90% mark, thanks to the excellently designed clinical trials conducted by various groups around the world, aided by the rapid progression of technology including genetic techniques, flowcytometry and pharmacogenomics [5], as well as vast improvements in supportive care. Unfortunately, even today 90% of children with ALL in the world's poorest 25 countries die in sharp contrast to the high-income countries where 90% of children get cured of the disease [2].

2.2 Incidence and Epidemiology in India and Global

ALL remains the most common malignancy of childhood, representing nearly one-third of all childhood cancers and 75% of all cases of childhood leukemia. The annual incidence is about 34 per million children in the United States [6], up to 40 per million among industrialized Western European, and 30–35 cases per million in Eastern European countries [7]. The incidence is lower in sub-Saharan Africa (20 per million). In India, a recent study compiling statistics from 24 population-based cancer registries (PBCRs) that clubbed India into six regions—North, South, East, West, Central, and Northeast, showed age-adjusted rates (AAR) of leukemia ranging from 0 (in some districts) to 62.3 per million (pm) for girls and 0 to 101.4 pm for boys in the age-group 0 to 14 years for the years 2012–2014, with most cases occurring in the North, South, and West regions of the country. However, these may not be fully representative, though they still give us the most specific data to date [8]. A rough projection from this data would give us a figure exceeding 10,000 new cases per year, which if accurate is higher than the population incidence seen in most developed countries. The peak age of ALL is 2–5 years and is more common in boys, the difference being greatest among pubertal children. White children are more commonly affected compared to blacks in the US.

2.3 Clinical Presentation in India and Global

ALL and its clinical presentation are best understood in the context of its etiology and interplay of genetic and environmental factors. While these are complex and largely obscure, many factors including genetic, immunological infections, and environmental factors are now considered causative. A prenatal origin of ALL was supported by finding TEL-AML1 (or ETV-RUNX1) fusion gene in some leukemic blasts in neonatal dry blood spot samples (Guthrie cards). This was however also found in 1% of all neonatal samples tested, a frequency 100 times higher than the incidence of ALL in children, suggesting a second hit mutation for leukemogenesis [9, 10]. The commonly encountered mixed-lineage leukemia (MLL) rearrangements occur in 80% of cases of infants with ALL and may be prenatal in origin [11]. ALL may also occur in identical twins, a risk which gradually decreases with age suggesting in-utero events like metastasis of leukemic clones—probably due to twin-to-twin metastasis, synchronous genetic events, or simultaneous prenatal exposure to environmental leukemogens [12]. Familial clustering of cases of ALL also lends support to the genetic origin of childhood ALL. Less than 5% of all childhood ALLs are associated with inherited genetic syndromes. Children with trisomy-21 are 15–20 times more likely to develop leukemia when compared to normal children [13]. Other less common syndromes predisposing to acute leukemias include Klinefelter's, Beckewith-Weideman syndromes, and germline BRCA2 mutations. Children with neurofibromatosis, Schwachman's syndrome are also reported to increase the risk of ALL. Syndromes leading to defective repair of chromosomes (Fanconi's anemia and Bloom's syndrome) have also been found to increase the risk [14].

Prenatal radiation exposure and higher birth weight have also been consistently associated with an increased risk of childhood ALL. Higher maternal age and history of fetal loss, parental smoking, and alcohol use, exposure to pesticides or solvents, and exposure to high levels of residential high power-frequency magnetic fields have all been proposed to enhance the risk of childhood ALL whereas perinatal maternal vitamin supplementation and population folate fortification have been associated with reduced risk. Infections have also been attributed to leukemogenesis; wherein delayed exposure to common infections (Greaves hypothesis) and population mixing (Kinlen's hypothesis) can potentially give rise to leukemia [15, 16].

The classification of ALL has also evolved over time from a simple morphological-based one, to a complex one incorporating immunocytochemistry, flow cytometry, and genetic and molecular characteristics. After several attempts to classify ALL by morphological criteria, the French-American-British (FAB) Cooperative Working Group came out with a classification system of ALL into ALL-L1, ALL-L2, and ALL-L3 [17]. Approximately 85% of children have ALL-L1, 14% have ALL-L2 and the rest 1% have ALL-L3. Representative morphology is depicted in Fig. 1. However, morphology does not correlate well with immunophenotype, cytogenetics, or DNA-microarray-based classification system [18]. In the current era with a wide range of risk predictors for the outcome of ALL at hand, the value of morphological classification in the treatment of these patients is fast losing its relevance [19].

With the advent of monoclonal antibodies, improvement in the enzymatic and fluorescent tagging of these antibodies, and the development of multi-parameter FACS, ALL has been classified immunophenotypically into two broad

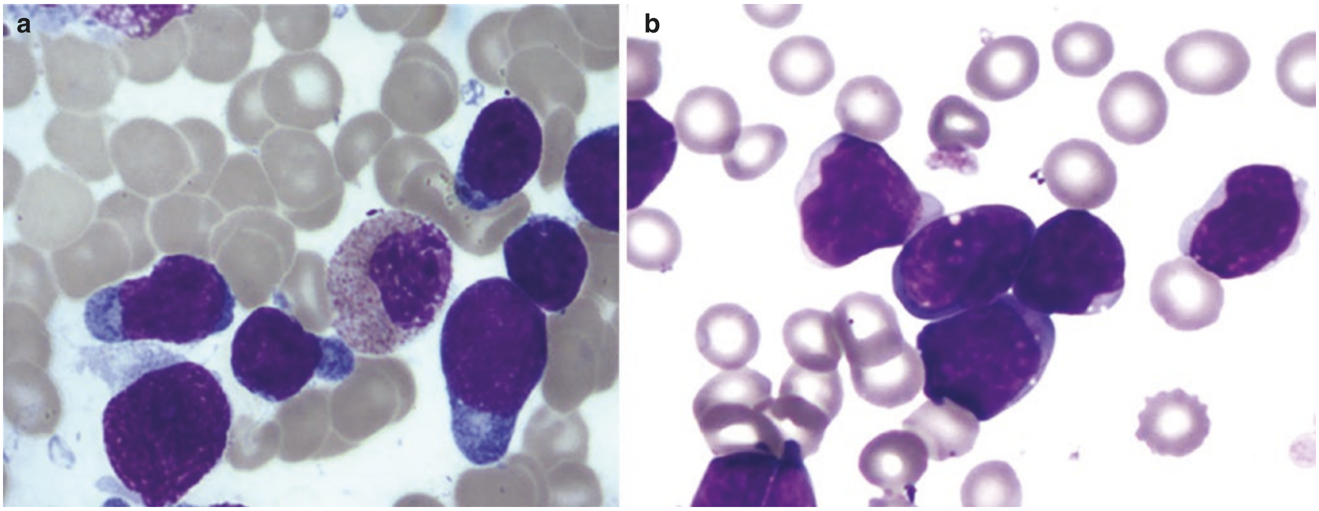

Fig. 1 Photomicrographs of blast morphology in ALL. (**a**) Precursor T lymphoblastic lymphoma/leukemia. (**b**) Precursor B lineage ALL. (Images courtesy of Dr. Nikhil Patkar, Hematopathology Laboratory, Department of Hematopathology, TMH, Mumbai)

classes: (1) B-cell ALL and (2) T-cell ALL, which in turn are further classified into several subgroups based on differences in immunophenotypic markers [19]. These subtypes of ALL have distinct genetic signatures which help to characterize these subgroups better and are of prognostic importance. Conventional cytogenetics, RT-PCR, fluorescence in-situ hybridization, and flow cytometry are increasingly used to detect specific fusion transcripts, gain or loss of cellular DNA content, or specific chromosomes with prognostic or therapeutic relevance [20]. Recent studies, including one by our group, have shown that an integrated genomic profile that includes copy number alterations may be prognostic in B-lineage ALL (B-ALL) [21].

However, from the therapeutic point of view, it is essential to classify ALL into three varieties—namely, precursor B-ALL, mature B-ALL, and T-cell ALL [20].

2.4 Precursor B-ALL

Traditionally, about 70–80% of B-ALL cases were classified by modal chromosomal number (ploidy) and specific genetic rearrangements into prognostically relevant subgroups. Now, with the advent of genome-wide analyses, virtually all B-ALL cases can be classified genetically. Hyperdiploidy (>50 chromosomes/blast cell) is associated with a good therapeutic response as these cells are more prone to apoptosis and accumulate more methotrexate polyglutamate. Hypodiploidy (fewer than 45 chromosomes per leukemia cell), found in less than 2% of cases, confers a poor outcome. Many translocations have been found to be of prognostic significance. TEL-AML1 (ETV-RUNX1 fusion) fusion the commonest translocation in precursor B-ALL portends favourable prognosis. MLL-AF4 arising due to t(4;11) is known to be a poor prognostic factor in childhood ALL, whereas MLL-AF4 due to t(4;11), MLL-ENL due to t(11;19) and MLL-AF9 due to t(9;11) are also associated with poor prognosis. Translocation t(9;22) fuses the BCR gene on chromosome 22 to the ABL gene on chromosome nine causing an abnormal ABL tyrosine kinase activity associated with increased proliferation and decreased apoptosis, this translocation is mainly found in B-ALL. Its incidence increases with age from 3% in children to nearly 25% in adults with ALL. It is considered high-risk due to resistance to standard chemotherapy and high postinduction MRD. However, the advent of targeted therapy using tyrosine kinase inhibitors (TKI) has improved outcomes to 75–80% 3-year EFS [22]. Recently, intra chromosomal amplification of chromosome21 (iAMP21) identified in about 2% of cases of precursor B-ALL, more in adolescents, has been identified as a high-risk disease responding poorly to standard therapy.

Using high-throughput techniques like single nucleotide polymorphism (SNIP) arrays and whole genome sequencing (WGS), deletions, amplifications, insertions, and other structural rearrangements were identified in patients with poorer outcomes with otherwise normal cytogenetic risk factors. Blasts with these mutations including IKZ1 mutations, PDGFR beta, ABL1, and ABL2 translocations were found to express genetic signatures similar to Ph+ve ALL and patients harboring these mutations benefit from TKI inhibitors [23].

2.5 T-Cell ALL

T-ALL being a biologically heterogeneous disorder compared to B-ALL has been less well characterized genetically. However, high throughput assays have identified new genetic signatures for T-ALL, though their clinical significance are being identified. More than 50% of cases of T-cell acute lymphoblastic leukemia have activating mutations that involve *NOTCH1*, a gene encoding a transmembrane receptor that regulates normal T-cell development. The presence of NOTCH1 mutation seems to predict a favorable outcome for T-cell ALL [24]. Epigenetic silencing of cyclin-dependent kinase inhibitor 2A (CDKN2A) gene leads to the inactivation of tumor suppressor genes leading to the neutralization of the TP53 and the retinoblastoma pathways in nearly 70% of the T-ALL cases. This mutation appears to confer a poor prognosis.

2.6 Special Types of ALL

2.6.1 Infant ALL

ALL of infancy appears to be biologically unique, arising from a very early stage of commitment to B-cell lineage and having unique genetic signatures as compared to older children. They express HLA-DR, but are usually negative for CD10 and other mature B-cell markers, instead of myeloid markers viz. CD15 may be positive. Structural abnormalities in chromosome 11 particularly rearrangements in band 11q23/MLL are frequently seen. The presence of MLL-AF4 rearrangement portends a poor prognosis despite intensified chemotherapy and HSCT [25]. Clinical trials specifically recruiting infant ALLs are looking into ways to improve the outcome including the use of novel agents for this poor prognosis disease.

2.6.2 Philadelphia-Chromosome Positive ALL

The presence of BCR-ABL translocation historically resulted in poor outcomes. Matched-related transplantation was recommended for all children with this subtype of ALL, and survival outcomes in the pretyrosine kinase-inhibitor era were 35 ± 4% (3-year EFS) with chemotherapy, and 57 ± 22% and 72 ± 19% with matched-related transplantation and matched-unrelated transplantation respectively [26]. The use of imatinib in combination with an intensive chemotherapy backbone improved results greatly to a 3-year EFS of 80 ± 11% [22]. The availability of second-generation TKIs has made it easier to treat Imatinib-resistant cases and Dasatinib is currently under trial for the treatment of pediatric ALL.

2.6.3 Adolescent ALL

Older adolescents 15–21 years of age have an inferior outcome as compared with that of children and younger adolescents with ALL, partly due to an increased incidence of Philadelphia chromosome-positive and T-cell ALL, lower incidence of *ETV6-RUNX1* fusion or hyperdiploidy, and poorer compliance [27, 28]. They also suffer more toxicities. However, it is also established that adolescents and young adults do consistently better when pediatric treatment protocols are used [29].

The presenting signs and symptoms in a child with ALL reflect the impact of bone marrow infiltration with the abnormal leukemic cells and the extent of extra-medullary involvement. Pallor (88%), fatigue, bone pain (23%), petechiae-purpura (48%), and fever (60%) are common symptoms at presentation. Lymphadenopathy (50%) and hepatosplenomegaly (68%) are frequent manifestations of extra-medullary leukemic involvement. T-cell ALL, seen in 15% of cases may present with a distinct set of sign-symptoms including an older child, commonly male with a very high total leukocyte count at diagnosis and commonly have a mediastinal mass [30]. A high proportion of children (10–15%) presenting with T-ALL may have CNS involvement at presentation.

Rarely children with ALL may present with signs and symptoms of unusual extra-medullary organ (ocular, urinary bladder, and pancreas) involvement. Hypereosinophilia with its attendant clinical features (Loeffler’s syndrome) is another well-documented but relatively rare feature at presentation, seen in association with translocation t(5;14). An elevated total leukocyte count of >10,000/mm^3 is seen in nearly 50% of the patients, with half of them having counts of more than 50,000/mm^3. Anemia (hemoglobin <10 g%) is seen in nearly 80%. Thrombocytopenia is seen in most patients, with nearly 75% of patients having a platelet count of <1,00,000/mm^3 [14].

2.7 Evaluation and Work-Up Including Risk Stratification

To establish a diagnosis of ALL a bone-marrow examination is necessary. Documentation of more than 25% lymphoblasts in the bone marrow by morphology and cytochemical staining (ALL− PAS±, Tdt+; AML− Peroxidase+, Sudan Black+) establishes ALL. Immuno-phenotyping by flow cytometry and genetic analyses further define and also stratify childhood ALL. Baseline organ function including liver function, renal function, cardiac function (echocardiography), and chest radiograph also need to be done pretreatment.

A variety of other laboratory abnormalities may be associated with childhood ALL. Many of these findings and their degree of severity merely reflect the leukemic cell burden, the extent of extra-medullary spread, or the excess proliferation and destruction (turnover) of the neoplastic cells. The rapid turnover of leukemic cells may lead to the classical “tumor lysis syndrome” (TLS) manifested by hyperuricemia, hypocalcemia, hyperphosphatemia, hyperkalemia, and deranged renal function. Children with high tumor burden (high initial leukocyte count, large lymphadenopathy, and hepatosplenomegaly) are predisposed to TLS, and it may precede or occur after initiation of therapy. Hepatic dysfunction may occur due to infiltration by leukemic cells and may not correlate with hepatomegaly. Patients may present with mild renal function derangements initially due to renal infiltration without any bearing on the disease outcome. Coagulation abnormalities may occur infrequently at diagnosis and disseminated intravascular coagulation (DIC) is rare [14].

2.8 Principles of Management (an Integrated Brief Overview of Rx Philosophy)

Treatment of ALL involves a remission-induction phase, followed by intensification/consolidation, interim-maintenance phase, and re-induction/delayed intensification followed by continuation/maintenance phase (Fig. 2).

2.8.1 Remission Induction Phase

The goal of this phase is to eradicate 99% of the initial leukemic burden, restore normal hematopoiesis, and improve the functional status of the patient [28]. The primary target is the medullary disease load. Combinations of glucocorticoids (prednisolone or dexamethasone), along with at least two other drugs (vincristine and L-asparaginase or an anthracycline) [31] are used. A three-drug induction is usually sufficient for most of the standard risk diseases, provided they receive an adequate postremission treatment. Children with high-risk or very high-risk ALL receive an induction comprising four or more drugs. The induction phase aims to induce complete morphologic remission, and preferably MRD remission, in 4–6 weeks.

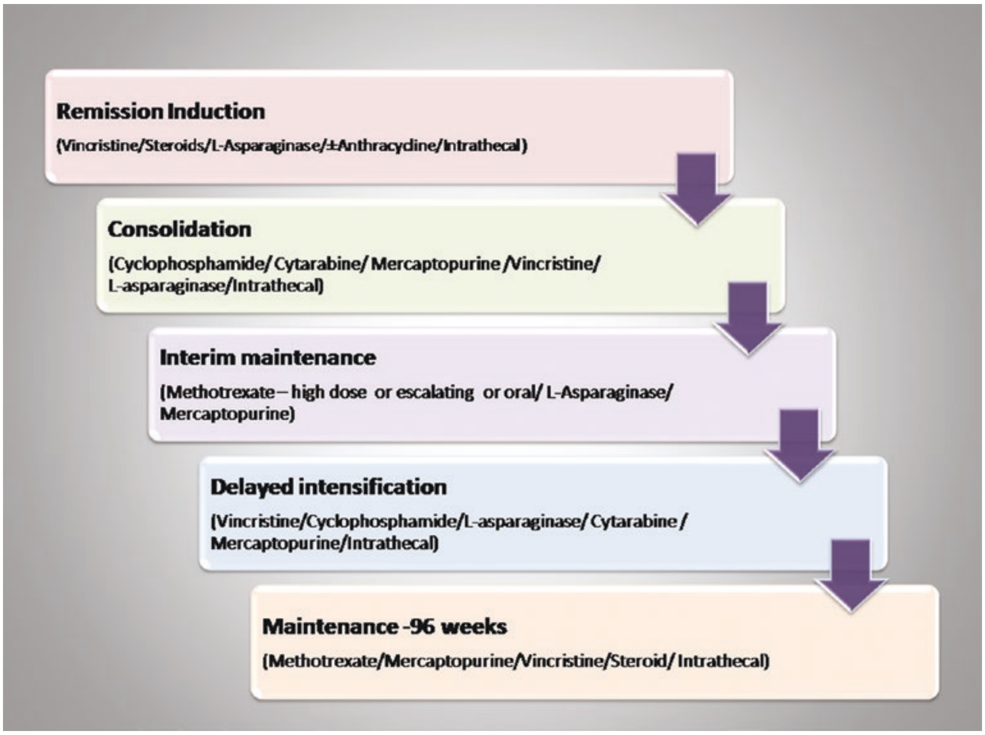
The treatment response is monitored during induction by various means: (1) Response to initial steroid prephase by peripheral blast count, (2) By bone marrow blast count at predefined time points between 1–3 weeks and 4–5 weeks of the start of induction, (3) By assessment of minimal residual disease (MRD) at various time points during induction like day 14 and/or day 35. A post-steroid day 7 peripheral blast count of >1000/mm^3, M2 or M3 marrow status (>5% and >25% bone-marrow blasts) or MRD >1% at day 14 are predictive of poor response and calls for a high-intensity post-induction therapy. In fact, response during induction (most importantly, MRD at day 35) is one of the single most important predictors for the overall outcome of ALL [13].

2.8.2 Intensification/Consolidation Phase

The aim is to eradicate minimal residual leukemia and drug-resistant leukemia from the system and the sanctuary sites (CNS, testes, etc.). Intensification is essential for all patients, but again there is no consensus on the best regimen or duration of treatment. Consolidation treatment is generally given soon after remission induction and includes drugs that were not included in induction (e.g., cyclophosphamide, cytarabine) [31].

2.8.3 Interim Maintenance

This is a phase of treatment following intensification and preceding re-induction, which varies according to the risk



Remission Induction
(Vincristine/Steroids/L-Asparaginase/±Anthracycline/Intrathecal)
Consolidation
(Cyclophosphamide/ Cytarabine/ Mercaptopurine /Vincristine/ L-asparaginase/Intrathecal)
Interim maintenance
(Methotrexate – high dose or escalating or oral/ L-Asparaginase/ Mercaptopurine)
Delayed intensification
(Vincristine/Cyclophosphamide/L-asparaginase/ Cytarabine / Mercaptopurine/Intrathecal)
Maintenance -96 weeks
(Methotrexate/Mercaptopurine/Vincristine/Steroid/ Intrathecal)

Fig. 2 Schematic presentation of phases of treatment (including commonly used drugs in each phase)

group of ALL and includes high-dose methotrexate with leucovorin and mercaptopurine (in case intensification comprised of non-HD-Mtx regimen) or escalating doses of methotrexate with pulses of L-asparaginase in high-risk B-ALLs [31, 32].

2.8.4 Re-induction/Delayed Intensification Phase

Delayed intensification, given within 2–3 months after remission, is clearly beneficial to all patients. The main purpose of this phase is to prevent disease relapse. More than one course of delayed intensification has not shown any additional benefit in outcomes but adds to the toxicity [33].

2.8.5 Continuation/Maintenance Phase

A prolonged maintenance therapy for 2 years is given for ALL, or even longer in some protocols. The aim is to prevent late relapses. Maintenance consists of daily 6-mercaptopurine (6-MP) and weekly methotrexate (Mtx). In some protocols, additional pulsed glucocorticoid, vincristine, and intrathecal therapy are administered. During continuation treatment with weekly low-dose methotrexate and daily mercaptopurine, tailoring the dosages of these drugs to the limits of tolerance has been associated with a better outcome [34].

2.8.6 Central Nervous System (CNS) Directed Therapy

CNS is the most important sanctuary site for leukemic cells and the commonest site of extra-medullary relapse of ALL, accounting for 30–40% of initial relapses. The penetration of systemic chemotherapy into the CNS is erratic, necessitating CNS-directed therapy. These include (1) the use of appropriate systemic chemotherapeutic agents in adequate doses, (2) intra-thecal therapy, and (3) judicious CNS radiation.

Intensified systemic therapy like dexamethasone, high-dose methotrexate, L-asparaginase, and 6-thioguanine used during various phases of treatment along with intrathecal therapy abrogates the need for prophylactic CNS radiation. Prophylactic radiation usually is given in a dose of 12 Gy. The need for CNS radiation (CRT) is currently limited to patients with overt CNS leukemia (CNS-3) only, in a dose of 18 Gy, many co-operative groups have stopped using cranial RT even in CNS-3 patients [35].

2.9 Medical Management and Monitoring

Patients should be stabilized and worked up rapidly on arrival (Table 1). Stabilization encompasses the prevention and treatment of tumor lysis syndrome, transfusion of blood products, and treatment of any co-existent infection. Patients presenting with compression of mediastinal/vital structures might need urgent initiation of cytotoxic drugs [14]. Patients need close monitoring for tumor lysis during the initial days of induction. Chances of infection during induction are high and need aggressive management, necessitating close follow-up and a good emergency response system. Postinduction follow-up is mostly guided by treatment protocol and the patient's clinical condition.

Response assessment is protocol based. However, the most important one is bone-marrow MRD at day 35 of induction (<0.01%—MRD remission/negative) [13]. Patients failing to clear MRD post-induction continue on high-risk protocol and undergo repeat assessment at the end of consolidation. Patients with persistent MRD positivity postconsolidation should be offered intensive chemotherapy followed by an allogeneic stem cell transplant.

The value of repeated bone-marrow MRD assessments once remission is achieved is questionable and is not recommended. It may be used to assess remission in a pre-SCT recipient [36]. Post therapy-completion, patients are followed-up clinically and with routine blood tests 3 monthly for the first year, then 6 monthly for 2 years, and annually thereafter.

2.10 Management Algorithms According to Risk Stratification

Risk-stratification of ALL is a comprehensive process involving the clubbing of clinical, pathological, and genetic factors, to which early response to therapy has also been added. Most contemporary protocols follow a similar strategy. There have been no new drugs in the treatment of ALL in the last three to four decades, though some drugs have newer, more effective formulations. Protocols have evolved around the world using the same few drugs in various combinations and schedules, more by trial and error. These have now been refined, along with great strides in supportive care measures, and evolved into strategies that are universally accepted. The first risk-stratification evolved from a workshop sponsored by the National Cancer Institute (NCI) in 1993, which involved all the major centers, and groups treating Pediatric ALL in the United States [37], now popularly called "NCI risk-groups". Different groups follow slightly different stratifications based on local strategies and needs. We present the one followed at our institute, a comprehensive amalgamation of the NCI risk criteria and current concepts (Table 2) [38].

2.11 Prognosis with Current Rx

Pediatric ALL has been one of the highly curable malignancies for several years now, with strides in each decade as outcomes improved from below 10% in the 1960s to above

Table 1 Diagnostic and initial management algorithm of PHL DMG at TMH

Assess if patient needs admission. Discussion with consultant.

Outpatient	**Inpatient** **(Discuss plan with consultant)**
Hr 0: - Assess need for transfusion	- IV fluids at 3L/m^2 (D5NS with I/2 NS if Na>138)
- Allopurinol (xyloric) (10 mg/kg/day)	- If in TLS, consider rasburicase (see TLS management) - L- Asparaginase if hyperleukocytosis ± Hydroxyurea in AML
- Syrup digene	-Maintain hemoglobin more than 7 gm% & platelets > 20,000/cmm.
- Plenty of oral fluids	- Antibiotics if fever ▪ Start chemotherapy once stable ▪ social worker review ▪ Nutritionist Review

Day 1:
- F/U daily or more frequently (as needed) with CBC, RFT, Ca, Mg, Phos, Uric acid
- Nutritional counseling
- To meet social worker

Day 2:
- Collect bone marrow reports
- Counsel the family /take consent
- To meet counseling nurse in OPD
- Diagnostic spinal tap with first IT on Day 2-8 based onprotocol (Mtx on Day 8 in ALL and TIT on day 2 in AML)
- Send CSF for cytospin, cell count, cytomorphology and biochemistry
- Start induction therapy (usually after admission)

Day8:
- Collect cytogenetics, CSF reports and blast cell count on PS

Day35:
- Bone marrow studies with MRD assessment

Reproduced with permission from the National Cancer Grid, first published in the NCG Guidelines for Common Cancers 2017 [39], based on Guidelines of the Pediatric Hemato-lymphoid Disease Management Group (PHL DMG) at Tata Memorial Hospital, Mumbai

90% in developed countries [39, 40]. Recently, with the increased use of more aggressive "pediatric-like" protocols in adolescents and young adults (AYAs), their prognosis too has improved somewhat [29, 41]. In India, the outcomes of Pediatric-ALL hovers around 60–70% in most centers. The challenges are the poor socio-economic status of the majority of our country with resultant issues like limited access to quality care, travel to referral centers and uprooting of families, malnutrition, limited availability of blood products, disruption of job, income, and education, and related problems that result in high rates of treatment abandonment, and also poor tolerance to toxic chemotherapy. A recent global survey identified many of these factors [42]. However, creating robust and comprehensive socio-economic support systems from government and non-government agencies can have a profound effect on decreasing treatment abandonment and

Table 2 Risk stratification of pediatric ALL and AML

Risk group	ALL	AML
Standard/ good risk	Age: 1–9 years Non-T-cell Prednisolone good response No high-risk cytogenetics WBC ≤50,000/mm^3	Inv(16) or t(16:16) t(8:21) t(15:17) Normal cytogenetics with Bi CEBPA or NPM mutation
Intermediate risk	Good risk But age ≥10 years or WBC ≥50,000/mm^3 Bulky disease Testicular disease	Normal cytogenetics +8 t(9:11) Other nondefined
High risk	All T-cell immunophenotype Prednisolone's poor response on D8 CNS disease on day 8 High-risk cytogenetics – MLL rearranged – Hypodiploidy (<45 chromosomes) – t(9:22), iamp21 – t(17:19) – MRD positive postinduction (>0.01%)	Complex (≥3 clonal) karyotype −5, 5q−, −7, 7q− 11q 23 [Non(9:11)] Inv(3) or t(3:3) t(6:9) t(9:22) Flt 3-ITD allelic ratio >0.4

Reproduced with permission from the National Cancer Grid, first published in the NCG Guidelines for Common Cancers 2017 [39], based on Guidelines of the Pediatric Hemato-lymphoid Disease Management Group (PHL DMG) at Tata Memorial Hospital, Mumbai

reducing mortality [43]. We showed that more than 250 patients of pediatric ALL who started treatment with us in 2010 had an overall survival (OS) of 67%, and treatment abandonment declined from above 30% in 2010 to consistently below 5% since 2013. In 2013, we also adopted the risk-stratified and treatment-response-based protocol of the Indian Pediatric Oncology Group (InPOG) [44], named Indian Childhood Collaborative ALL Protocol (ICiCLe), and piloted it from March 2013 to February 2018. An interim analysis of 726 children showed projected 3-year OS was 90.4 ± 1.4% (median follow-up—23 months), while EFS was 70.7 ± 2.3%. Seventy percent of mortality occurred in intensive phases of treatment, and 86% of all events in non-SR arms. Three-year OS for standard-risk patients exceeded 95% [45].

2.12 Management of Recurrent Disease Including Specific Palliative Measures

Despite excellent results of contemporary pediatric ALL protocols, 15–20% of pediatric ALL and nearly 30–45% of adolescent and young adult ALL cases relapse [41, 46]. Being one of the most commonest malignancies in children, the relapse burden is commensurately high, making ALL-relapse the fourth most common pediatric malignancy [47]. With the increasing use of MRD evaluation, end-induction levels above 0.01% predict EFS of 30–59%, while those who are negative (<0.01%) have more than 88% EFS [48]. Treatment decisions are now based on MRD assessed by FCM or molecular techniques [36, 48]. Current protocols allow for a risk-adapted approach and treatment escalation in those who are MRD-positive at the end of induction. These patients are reassessed after consolidation. MRD-positive at this time are considered chemotherapy-refractory requiring alternate strategies.

Treatment of relapse/refractory ALL is difficult as it involves intensive chemotherapy ideally followed by an allogeneic stem cell transplant (Allo-SCT) in patients with high-risk features at relapse. Allo-SCT however, is capital and human-resource-intensive, and most crucially requires a matched donor, preferably a sibling (matched sibling donor, MSD), with the same human leucocyte antigen (HLA) signature in at least 10 loci. Being somatically inherited, the chances of two siblings being HLA matched is less than 25% depending on family size and ethnic/familial cloistering [49]. Matched unrelated donor (MUD) SCTs are several folds more expensive [50]. Most donor registries are in developed nations and of differing ethnicities resulting in lower chances of matching in Indian patients [51]. Moreover, the timing of the relapse with respect to disease-free interval affects the chances of a successful Allo-SCT. Early medullary relapses defined as occurring within 36 months of first remission (CR1) have only 20–40% successful outcomes, while extramedullary relapses or those beyond 36 months of first remission may have 60–70% outcomes [46]. Patients need to be in remission again (CR2) with MRD-negative status prior to SCT [52]. This involves intensive chemotherapy to achieve and sustain CR2 till such Allo-SCT. As number of centers doing Allo-SCTs are still few when compared to the need, this often proves challenging and extremely toxic for the patients. Allo-SCT itself carries significant morbidity and TRM, and many patients may suffer long-term complications especially GVHD and infections related to long-term immunosuppression, which tend to increase over time [53]. Unlike developed nations, in India, the expenses and technical difficulties involved result in less than 10% of patients who might benefit from an SCT opting for one, and only a fraction making it through the entire process. Allo-SCT, being an extensive topic in itself, is outside the purview of this chapter.

Developments in genetic engineering, biotechnology, and immunotherapy have brought forth many ALL-specific therapies including monoclonal antibodies and engineered cellular immunity against cell surface markers of leukemic blasts. They are mostly in early-phase human studies and some are now licensed and in phase-3 clinical trials. These include anti-CD19 antibodies (Blinatumomab), anti-CD22 antibodies (Inotuzumab and Epratuzumab), and CD19/CD22 or CD19 and CD22 bispecific Chimeric Antigen Receptor (CAR) T-cells, which have shown promising efficacy in managing relapsed/refractory disease [54].

3 Acute Myeloid Leukemia

3.1 Introduction

Myeloid is derived from the Greek word 'Muelos' meaning bone marrow. Cells belonging to the granulocytic (neutrophilic, eosinophilic, basophilic), monocytic/macrophage, erythroid, megakaryocytic, and mast cell lineages comprise the Myeloid series. Therefore, malignancies of the myeloid series are a heterogeneous group of disorders, caused by genetic aberrations in hematopoietic stem cells with unlimited self-renewal capacity with a certain degree of myeloid differentiation. These genetic aberrations are divided into Class I and Class II mutations. Class I mutations confer a proliferative and anti-apoptotic advantage, while class II mutations cause inhibition of normal hematopoietic cell differentiation [55]. The leukemic stem cell (LSC) is difficult to eliminate, and a major cause of relapse [56, 57]. Intensification of therapy to eliminate the LSC increases the risk of toxic deaths during and after treatment. Prolongation of chemotherapy has not helped either [58]. The UK-MRC trials showed five courses of chemotherapy were not superior to four [59]. Allogeneic HSCT in CR1 for high-risk diseases with the aim to exploit the graft-versus-leukemia effect is being used as a strategy to improve relapse-free survival [58, 60].

Myeloid leukemias are acute in more than 95% of children. Juvenile myelomonocytic leukemia is exclusive to the pediatric age group and has poor outcomes worldwide, with transplantation in CR1 offering some benefits [61, 62]. About 10% of children with Downs' syndrome have transient abnormal myelopoiesis (TAM), and 20% of them develop acute megakaryoblastic leukemia (AMKL), which often has good outcomes with lower doses of chemotherapy because of higher sensitivity to them [63]. Myelodysplastic syndrome is rare in children, but AML associated with underlying bone-marrow failure syndromes is a different topic beyond the scope of this chapter.

3.2 Incidence and Epidemiology in India and Global

In children, ALL is five times more common than AML. About 10,000 new cases of pediatric AML are registered worldwide [64]. In our 5-year experience, we have seen about 2262 cases of ALL and 517 cases of AML with a ratio of 4.3:1, which mirrors the global experience. A comprehensive review of acute leukemias from 24 PBCRs in India, gave data on acute leukemias (refer to section of ALL), but did not segregate AML [8].

3.3 Clinical Presentation in India and Global

These patients often present with hyperleukocytosis, and with infections due to prolonged neutropenia and severe malnutrition. In general, the presentation of AML can vary, but in India, most are present with advanced-stage disease. Pallor and fatigue, petechiae and mucosal bleeds, and recurrent fevers mostly bacterial and fungal, are common. Bone pain is not uncommon and patients might present with a limp or rib pain or back pain. The extramedullary disease may present with (1) hepatosplenomegaly more frequent in infants, (2) leukemia cutis with blueberry muffin appearance in infants with monocytic differentiation, or (3) granulocytic sarcoma of the orbit and epidural area mostly in AML M4 and M5. Involvement of the testes is rare. In one series, about 20% of patients had myeloid sarcoma frequently associated with t(8;21), and had a better outcome even in the absence of t(8;21) [65]. CNS involvement at diagnosis occurs in 15% of patients.

3.4 Evaluation and Work-Up Including Risk Stratification

A peripheral smear can raise suspicion for acute leukemia and is a critical investigation, especially for acute promyelocytic leukemia. A detailed evaluation with bone-marrow aspiration and biopsy is essential. Myeloperoxidase stains are positive in the blasts. Morphology of a bone-marrow biopsy can identify features of myelodysplasia, or underlying fibrosis as in the case of AMKL. Immune phenotyping at diagnosis is valuable to confirm the FAB phenotype and is more useful for MRD monitoring to assess response to treatment. Chromosome karyotyping and molecular cytogenetics help in risk stratification, prognostication, and identification of associated genetic predispositions. Currently, WHO classification uses specific and recurrent cytogenetic abnormalities to stratify AML as:

- AML with recurrent genetic abnormalities
- AML with myelodysplasia-like features
- Therapy-related AML
- AML not otherwise specified
- Myeloid sarcoma
- Myeloid proliferation related to Down syndrome

Table 3 Classification of AML with characteristics

AML FAB type	Chromosomal abnormality	Affected genes	Characteristics
M0			Less common in pediatrics
M1, M2	t(8;21)(q22;q22)	RUNX1-RUNX1T1	MPO+, Auer rods, granulocytic sarcoma, no HSCT if t(8;21)+ Standard risk
M3 M3v	t(15;17)(q22;q12) t(11;17)(q23;q12)	PML-RARα PLZF-RARα FLT3 aberrations	Coagulopathy, ATRA sensitive, favorable prognosis, no HSCT ATRA resistant, poor prognosis Hyperleukocytosis, ATRA sensitive, favorable prognosis
M4eo	inv(16)(p13;q22) t(16;16)	MYH11-CBFβ	CNS leukemia; eosinophilia with basophilic granules favorable prognosis, no HSCT Standard risk
M4, M5a M5b	t(11q23) anomalies t(8;16)	MLL rearrangements MYST3-CREBBP	Infants or young adults, hyperleukocytosis, erythrophagocytosis and coagulopathy, granulocytic sarcoma, and secondary leukemia after topoisomerase II inhibitors t(4;11) are specially associated with infants presenting with CNS and skin involvement
M6		Chromosome 5&7	Less common in paediatrics, >50% blasts are erythroblasts, Flow + glycophorin A
M7	t(1;22) Trisomy 21	RBM15-MKL1	AML in infants with Down syndrome, myelofibrosis, favorable prognosis, CD41+, CD61+ Non-Downs AMLM7 without t(1;22) have a poor prognosis
M2, M4, MDS	t(6;9) inv(3) t(3;3)(q21;q26)	DEK-NUP214 EVI1	Basophilia Prior to MDS, thrombocytosis and abnormal platelets
MDS	−7/del(7)(q22-q36) −5/del(5)(q11-q35) +8		Exposure to toxins, MDS progressing to AML, less common in children

Many clinicians still find it easy to correlate FAB classification with clinical features. Table 3 [66] shows the correlation between different AML FAB subtypes and underlying chromosomal aberrations and associated clinical characteristics.

3.5 Principles of Management (an Integrated Brief Overview of Rx Philosophy)

Chemotherapy for AML consists of two cycles of chemotherapy for remission-induction, followed by postremission therapy which includes two cycles of consolidation for standard-risk patients and HSCT for high-risk patients. CNS prophylaxis with triple intrathecal chemotherapy keeps CNS relapse rate <5%. Most cooperative group trials use aggressive induction with 3+7 induction regimen with anthracycline for 3, and cytarabine for 7 days, with or without etoposide or thioguanine [58, 59]. This is followed by postremission therapy with high-dose cytarabine (HiDAC)-based regimens. Newer agents to achieve better remission induction while minimizing anthracycline-related cardiotoxicity are incorporated in the different phases of treatment [67].

3.6 Risk Stratification

Patients with recurrent genetic abnormalities t(8;21) and inv [16] and double mutant CEBPA are considered standard/low risk [68]. Patients with complex cytogenetics, MDS/monosomy or del 5 and 7, FLT3-ITD are considered high-risk patients and are eligible for transplant in CR1. Patients who do not qualify for either, are classified as intermediate-risk. These patients are managed based on the MRD status at the end of the first and second cycles of chemotherapy. The St Jude group uses MRD <1% after the first induction cycle and <0.1% at the end of induction as the cutoff for decreased risk of relapse [58]. The risk-stratification strategy at TMH is given in Table 2.

3.7 Treatment at TMH

At TMH we often see patients who present late. High white counts at presentation are common, with a risk of TLS. Cytarabine and hydroxyurea have been used to reduce the leukemia burden before definitive chemotherapy. We have seen good results with L-asparginase in rapidly reducing the leukemia burden without TLS. We use a standard 3+7 Induction for all AMLs. A bone-marrow morphology is done on day-10. If any blasts are present, the patient gets additional Ara-C 8 g/m^2 (four divided doses 12 hourly × 4) on day-10 and 11. Bone-marrow studies are repeated on count recovery in either case. Frank induction failures are shifted to a salvage regimen with the Cladarabine-Cytarabine combination. The rest are continued on high-dose cytarabine (HiDAC) blocks. MRD assessment is done post-induction and if positive, repeated at the end of the first consolidation regimen. Patients MRD-negative by the end of the first or second cycle of chemotherapy get a total of three HiDAC blocks. They then get one-year maintenance of oral metronomic chemotherapy (OMCT) with 6-thioguanine (40 mg/m^2) and oral Etoposide (50 mg/m^2) 3 weeks followed by a 1-week break making one cycle [69, 70]. Patients not achieving MRD-negative status by the end of the second cycle of intensive therapy, are changed to the salvage regimen as above. All patients needing a salvage regimen are counseled for Allo-SCT. Patients who are MRD-positive after two cycles of salvage regimen are considered palliative. All high-risk patients are also counseled for SCT in the first remission. In patients with very poor general condition at presentation due to severe malnutrition, invasive fungal infections, or multi-drug resistant organism (MDRO), we use the OMCT strategy upfront, allowing them to stabilize, while reducing the disease burden and creating an opportunity to withstand subsequent standard intensive therapy. OMCT is also used to palliate patients failing to achieve remission as it allows them to go home with a reasonable quality of life till the inevitable progression.

We have also investigated the use of disease-modifying agents in AML. Sorafenib is an oral biaryl-urea derivative that can inhibit the Ras/Raf/MAP/ERK signaling pathway. It also inhibits tyrosine kinases like VEGFR, c-kit, PDGFR-β, and FLT-3. Due to its potent Tyrosine-kinase inhibitory activity, especially, its ability to inhibit FLT-3 kinase, we use it in combination with chemotherapy for patients with FLT3 mutations (FLT3-ITD). A very important aspect for improvement in outcomes would be supportive care, which can have a deep impact on disease-free survival in AML, and other pediatric cancers [43].

3.8 Relapsed AML

Once relapsed or refractory, AML is difficult to treat. Remission induction with Cladarabine Ara C has been somewhat successful in our hands but the remission is short-lived unless patients undergo Allo-SCT.

3.9 Future Directions

Immune-based therapies are being explored to improve outcomes for AML since we have hit a ceiling with the amount of chemotherapy that can be given. Some groups are using gemtuzumab ozogamicin to target the C33-positive leukemic stem cells. At St. Jude, haploidentical KIR mismatched NK cells are being used as consolidation therapy to prolong remission [60]. Still, others are exploring the use of chimeric antigen T cells directed against sCD123 and CD33 that might be able to get rid of the leukemic stem cells to achieve sustained remission.

4 Acute Promyelocytic Leukemia

4.1 Introduction

Acute promyelocytic leukemia (APML/AML-M3) is characterized by (a) typical morphology of blasts, (b) t(15;17), and (c) specific coagulopathy [71]. A sound understanding of the biology of APML has changed it from having the worst to the best prognosis among AML subtypes.

The reciprocal translocation t(15;17) of retinoic acid receptor-α (RARα) locus on chromosome-17 and the PML locus on chromosome-15 results in the PML-RAR-α fusion protein, which is a dominant negative inhibitor of promyelocytic leukemia protein and retinoic-X receptor (RXR) present in macromolecular nuclear organelles called PML oncogenic domains (POD), and disrupts their localization. All-trans retinoic acid (ATRA) binds to the RARα domain leading to re-localization of the PML and RXR proteins rescuing the cell from differentiation arrest. Arsenic, on the other hand, binds to the PML domain causing degradation of the fusion protein an effect similar to ATRA. In addition, Arsenic causes degradation of the wild-type PML protein leading to apoptosis of the cell. The non-cross-resistant mechanism of action of these two agents has led to improved outcomes in APML [72].

4.2 Incidence

APML accounts for about 10–15% of patients with AML. Data in the Indian setting is lacking. At TMH 15% of AML patients had APML.

4.3 Principles of Management

Treatment of APML has evolved in three phases. Pre-ARTA era, ATRA + chemotherapy era, and ATRA + Arsenic era. In the pre-ATRA era high-dose anthracyclines were used in combination with cytarabine with CR rates of 65–80% of which 50% relapsed. Early death due to coagulopathy or chemotherapy resistance was a major cause of mortality [71].

The introduction of ATRA upfront allowed better control of coagulopathy. The combination of ATRA and chemotherapy resulted in 80–90% CR rates and could result in long-term relapse-free survival of about 70% [73]. Later, the focus shifted to reducing anthracycline-induced cardiomyopathy and improvement of quality of life. LoCoco in 1993 showed that a combination of ATRA + Arsenic might even be superior to ATRA + chemotherapy. In the Arsenic + ATRA era, Sanz risk stratification and maintenance gradually lost their significance. All patients received the induction and consolidation with ATRA + arsenic. Patients with high tumor burden received chemotherapy or biological agents like Gemtuzumab ozogamicin [74]. In the MRC AML17 trial, ATRA + Arsenic had very good CR rates and a cumulative incidence of relapse of 1% [75]. In all these trials, pediatric patients were enrolled and analyzed separately on the same protocol. In the ATRA trials, pediatric patients had a higher incidence of pseudotumor cerebri and the dose of ATRA was reduced to 25 mg/m^2 with no difference in efficacy [75, 76].

A patient presenting with characteristic coagulopathy and increased promyelocytes on a peripheral smear should be immediately started on Arsenic or ATRA as per the local protocol. It is justified to stop it later if the suspicion proves to be incorrect. Morphologically two different variants exist, the classic, and M3v microgranular variants. The latter is associated with FLT3 mutation or ITD and hyperleukocytosis [77]. A quick FISH test to look for t(15;17) is useful but RT-PCR is the gold standard for diagnosis and response assessment. Five percent of APML patients present with atypical breakpoints with alternative chromosomal alterations, and might not be sensitive to ATRA. However, arsenic and ATRA have non-cross-resistant pathways and their combination might help in these cases.

4.4 Management and Monitoring

Patients with APML are at high risk of DIC. Monitoring of blood counts and PT/PTT/INR at 6–8 hourly intervals is essential. Transfusion of platelets to keep count above 30,000/μL and fibrinogen above 1.5 g/L using FFP or cryoprecipitate helps prevent catastrophic bleeding. ATRA causes differentiation of promyelocytes and reduces the risk of coagulopathy but predisposes to differentiation syndrome. Chemotherapy, on the other hand, causes tumor lysis and leads to coagulopathy. Therefore, a combination of ATRA and chemotherapy is used to achieve a fine balance. Children are at a high risk of pseudotumor cerebri and a lower dose of ATRA at 25 mg/m^2 is used. Arsenic can cause hepatotoxicity and prolonged QTc interval predisposing to arrhythmias. Monitoring electrolytes, especially potassium, calcium, and magnesium are helpful to prevent arrhythmia. In case of hepatotoxicity, prolonged QTc, differentiation syndrome, or pseudotumor cerebri, withholding treatment for a few days manages the side effect appropriately and it can then be restarted at a lower dose [74–76, 78].

4.5 Treatment Algorithm

4.5.1 Induction

Arsenic 0.15 mg/kg daily + ATRA 25–45 mg/m^2 is given in two divided doses until complete hematological remission or day-60. Anthracycline can be given in case of hyperleukocytosis or added if WBC count rises to >6000 at day-5, >10,000 at day-10, or >15,000 on day-15 since they are at higher risk of differentiation syndrome [71].

4.5.2 Consolidation

Arsenic is given for 4 weeks on 4 weeks off for 4 cycles. ATRA is given 2 weeks on and 2 weeks off for 7 cycles.

4.6 Common Toxicities

Differentiation syndrome is seen after introducing ATRA or arsenic, and the patient presents with respiratory distress, sudden weight gain, pleural and pericardial effusion, hypotension, and cardiac or renal failure. Dexamethasone at 5 mg/m^2/dose twice a day and stopping ATRA and arsenic until resolution of differentiation syndrome and restarting at 50% of the dose with escalation over 2–3 days is an effective treatment.

About 10% of children mostly below 10 years of age present with headache blurry vision nausea and vomiting. Computerized tomography (CT) scans of the head show no evidence of bleed. This has led it to be called "pseudotumor cerebri." ATRA and arsenic should be stopped until the resolution of symptoms and acetazolamide can be started at 8 mg/kg up to 250 mg three times a day [78].

Arsenic can cause prolonged QT interval. Electrolytes and ECG are monitored on a weekly basis and withheld if QTc is more than 0.45 s.

4.7 Management of Recurrent Disease

Patients who relapse of non-arsenic protocols are given arsenic as a single agent and autologous transplant can be considered in CR2. For patients who have received arsenic previously arsenic + ATRA can be given in combination with Bortezomib with a 3-year EFS of 92% [79].

5 How We Do It at TMC

From the mid-1980s till 2013, we treated all patients of ALL on the MCP841 protocol, first introduced in India as a medium-intensity protocol meant for out-patient delivery and did not incorporate high-dose methotrexate. Initial results on it improved outcomes to above 50% and reduced relapse rates compared to those treated with a less intensive protocol [80]. Later, outcomes improved to 67% [43]. However, the protocol underwent several modifications from its original form in this period. Since March 2013, we have adopted the ICiCLe protocol as a pilot, initially only for B-ALLs. As shown earlier, this may be able to result in 5-year OS in the range of 75–80%, as 3-year results have been encouraging [45]. However, the impact of improved supportive care strategies including socio-economic support, aggressive nutrition intervention, uninterrupted availability of blood products, an effective social worker team to track and retain patients, and even continued schooling, in improving outcomes, cannot be ignored [43]. Effective March 2018, we are offering all our patients with B-cell ALL, T-cell ALL, and lymphoblastic lymphomas to participate in the trial. We are still using the previous multicentre protocol (MCP 841) to treat children with Mixed phenotype acute leukemias (MPALs) as it contains consolidation with high-dose cytarabine that has proved useful in this poor prognosis risk group [81]. To address the issue of relapsed/refractory B-ALL we are in the process of developing indigenous CAR T-cell therapy in collaboration with the Indian Institute of Technology-B (IIT-B) in Mumbai, which may prove effective at affordable costs.

For acute leukemias, we have formulated a diagnostic and initial management algorithm that can be common to all of them until they are started on individual protocols as already discussed (see Table 1).

PET-CT	Positron emission tomography-computerized tomography
RER	Rapid early responder
SER	Slow early responder
SPPD	Sum of the product of perpendicular diameters
SST	Secondary solid tumors
USG	Ultrasonography
VAMP	Vinblastine, doxorubicin, methotrexate, prednisone

1 Introduction

Hodgkin lymphoma (HL) is one of the pediatric malignancies with excellent survival [1]. It is fair to say that in the race to cure malignancies, HL was among the first to wear the "curable cancer" tag. Initial treatment regimens in children were similar to those used for adults, but the differential impact of long-term morbidities seen especially in children and young adults including secondary malignancies, permanent gonadal toxicity leading to infertility, and cardiotoxicity led to successive risk-based, gender-based, and response-based trials in children. From combined-modality treatment

involving chemotherapy and radiotherapy to all, these trials have helped tailor treatment by reducing chemotherapy in lower-risk groups and avoiding radiotherapy in those children with good responses. Newer trials are ongoing, incorporating targeted agents in frontline therapy. Significant progress has also been achieved in the relapsed and refractory setting with improved survival.

2 Incidence and Epidemiology in India and Global

HL accounts for 5–6% of pediatric malignancies [2] with an annual incidence of about 0.5 cases per 100,000 children in the United States and European Union [3]. In India, lymphomas often exceed CNS tumors in children as opposed to the developed world, with Hodgkin lymphoma exceeding non-Hodgkin lymphoma, which seems to result mainly from the higher incidence of HL in male children <14 years of age [4].

Epidemiologically, there are three distinct forms of HL: a childhood form (≤14 years), an adolescent and young adult (AYA) form (15–34 years), and an older adult form (55–74 years). In the developed world, the early peak occurs during the middle-to-late 20s compared to the developing world where it is seen before adolescence [5]. Reports from various resource-limited countries show that there is an increased incidence of HL before five years compared to the industrialized countries [6]. There is slight overall male preponderance in the childhood form, while gender distribution is almost equal among the AYA group.

In Western countries, 75% of newly diagnosed patients have early disease at presentation (stage I–II) while more than half of the patients in the developing world have advanced disease (stage III–IV). The most common histologic subtype is mixed cellularity probably related to early Epstein–Barr viral (EBV) exposure compared to the developed world where nodular sclerosis dominates in the AYA population [4]. The risk of HL is also increased among individuals with primary immunodeficiencies, HIV infection and those on post-transplant immunosuppression [7–11].

3 Clinical Presentation in India and Global

Most patients present with painless lymphadenopathy (80%), commonly involving the cervical or supraclavicular area. These lymph nodes are firm, rubbery, non-tender, and tend to be matted. There is typically contiguous spread along adjacent lymph node regions as opposed to non-Hodgkin's lymphoma. The mediastinal disease is seen in 75% of the AYA population compared to 35% in younger children reflecting the different histological sub-types in these age groups. Primary sub-diaphragmatic disease is rare and is seen in <3%. Fever (oral temperature >38 °C), weight loss (≥10% body weight within preceding six months), and drenching night sweats are constitutional symptoms that have prognostic significance [10].

Laboratory findings are nonspecific and include anemia mostly due to failure of iron store mobilization, elevated erythrocyte sedimentation rate (ESR), neutrophilic leukocytosis, lymphopenia, eosinophilia, thrombocytosis, and monocytosis.

Paraneoplastic syndromes are rarely associated with HL such as nephrotic syndrome, autoimmune hemolytic anemia, neutropenia, thrombocytopenia (ITP), polymyositis, idiopathic cholestasis, and limbic encephalitis [11]. Autoimmune hemolytic anemia may be Coombs positive and may be diagnosed before, at the time of disease diagnosis, or after therapy. ITP may develop after treatment completion and does not predict relapse. Its treatment and response are similar to non-HL-related ITP.

4 Evaluation and Work-Up Including Risk Stratification

4.1 Diagnosis

An excision biopsy of the suspected lymph node is preferred as it helps evaluation of Hodgkin's and Reed Sternberg (HRS) cells and the architectural changes seen in the different subtypes. In case of inaccessible sites where excision biopsy is not possible like retro-peritoneum or mediastinum, a core needle biopsy can be performed. HRS cells form only 0.1–10% of the tumor tissue, the bulk of which is inflammatory cells, therefore fine needle aspiration (FNAC) does not provide sufficient diagnostic tissue material and should be avoided. The diagnosis is established by histology and immunohistochemistry (IHC). HL is a B-lineage lymphoma arising from germinal center B cells characterized by clonal tumor cells in a polymorphous inflammatory background comprising T-lymphocytes, eosinophils, plasma cells, neutrophils, histiocytes, and fibroblasts [12].

HL can be classified into two main pathologic classes [12].

- Classical HL (cHL)
- Nodular lymphocyte predominant HL (NLPHL)

cHL is further subdivided into four types as below

- Nodular sclerosis
- Mixed cellularity
- Lymphocyte rich
- Lymphocyte depleted

4.2 Immunohistochemistry

HRS cells express CD30, with 70% of patients with CD15 positivity and 10–20% with CD20 positivity. Generally, they are negative for CD45, B-lineage antigens (CD19, CD79a, OCT2, BOB1) and bcl-6 [13]. Approximately 98% have dim PAX-5 expression and they often express plasma cell molecules (CD138, MUM1) and molecules involved in B-T cell interactions (CD80, CD86, MHC-II) [14, 15].

In nodular lymphocyte predominant HL (NLPHL), the HRS cells are mononuclear with convoluted and lobulated nuclei and hence called popcorn or lymphocytic and histiocytic cells. They lack non-B cell antigens CD30 and CD15 and express CD45, CD20, and B-lineage antigens.

Diagnostic work-up should include

- Clinical evaluation with a detailed history and physical examination: All the lymph node regions including the Waldeyer's ring should be examined and their sizes documented. An ENT examination should be sought in case of suspicious involvement of Waldeyer's ring as involvement is based on clinical judgment rather than imaging in this scenario.
- Laboratory investigations:
  - Complete blood counts (CBC) and differential leukocyte counts and erythrocyte sedimentation rate (ESR)
  - Lactate dehydrogenase (LDH), liver function tests (LFT), and serum creatinine
  - Beta 2 microglobulin
  - Coagulation tests
  - Baseline viral screening (HBsAg, HIV, anti-HCV)
  - Baseline IgG levels
- Chest X-ray: An upright posterior-anterior chest X-ray (bulky mediastinal disease is as defined in the section on staging below).
- Ultrasonography (USG) abdomen to look for splenic lesions in case of doubt on PET-CT.
- F^{18} FDG positron emission tomography-computerized tomography (PET-CT) to stage the disease. This modality combines functional and anatomic characteristics and is used for staging and monitoring the disease [16–18].
- The five-point scale also referred to as the Deauville criteria [19, 20], which is a visual PET criteria, has been used for baseline staging and response assessment, with mediastinal blood pool utilized as the reference activity in baseline and late response assessment scans and liver blood pool being utilized in early response assessment scans. The five-point scale is as follows:
  - Score 1—no uptake
  - Score 2—uptake less than or equal to the mediastinum
  - Score 3—uptake greater than the mediastinum, but less than the liver
  - Score 4—uptake moderately higher than the liver
  - Score 5—uptake markedly higher than the liver
  - For baseline staging, FDG PET positivity is defined as scores three, four, and five. For response assessment scores four and five are considered positive
- Bone marrow aspiration and biopsy: If PET-CT is not available, bone marrow studies are to be done for those with B symptoms or Stages III and IV. PET-CT has high sensitivity (96.9%) and specificity (99.7%) in detecting bone marrow involvement at baseline, with focal involvement highly predictive of marrow involvement [21].
- Bone scan: Is indicated if PET-CT is not available and the child has bone pains, otherwise unexplained elevated alkaline phosphatase.
- CT (computerized tomography)/MRI (magnetic resonance imaging) of neck, chest, abdomen, and pelvis—if PET-CT is not available.
- Echocardiography (optional).
- Fertility preservation is recommended wherever feasible
  - Sperm cryopreservation in post-pubertal boys
  - Oophoropexy in girls if considered for pelvic radiotherapy

4.3 Assessment of Involved Regions and Staging

HL spreads by contiguous lymph node spread, which is the basis of the Ann Arbor staging system [22, 23] described in Table 1.

4.4 Risk Stratification

Disease risk assignment varies among the different trial groups [24] as is shown in Table 2. Broadly risk groups are assigned as low-risk intermediate and high risk based on stage, presence of B symptoms, involvement of extra-nodal sites, and presence or absence of bulky disease. Elevated ESR is a risk factor in the EuroNet consortium.

Table 1 The sub-stage classifications A, B, E, S, and X amend each stage based on defined features [22, 23]

Stage I	Involvement of a single lymphatic site (i.e., nodal region, Waldeyer's ring, thymus, spleen) (I); or localized involvement of a single extra lymphatic organ or site in the absence of any lymph node involvement (IE)
Stage II	Involvement of two or more lymph node regions on the same side of the diaphragm (II); or localized involvement of a single extra lymphatic organ or site in association with regional lymph node involvement with or without involvement of other lymph node regions on the same side of the diaphragm (IIE)
Stage III	Involvement of lymph node regions on both sides of the diaphragm (III), which may also be accompanied by extra lymphatic extension in association with adjacent lymph node involvement (IIIE) or by the involvement of the spleen (IIIS) or both (IIIE, S)
Stage IV	Diffuse or disseminated involvement of one or more extra lymphatic organs, with or without associated lymph node involvement; or isolated extra lymphatic organ involvement in the absence of adjacent regional lymph node involvement, but in conjunction with disease in distant site(s). Stage IV includes any involvement of the liver or bone marrow, lungs (not E), or cerebrospinal fluid

B, B symptoms; A, absence of B symptoms; S, spleen involvement; E, extra-nodal extension, which most commonly involves lung, pleura, pericardium, or bone when there is contiguous extension of lymph node disease or the site is proximal to an involved draining lymph node. X, the bulky disease is defined differently by various study groups. Bulky peripheral lymphadenopathy is defined as a single or conglomerated lymph nodal mass >6 cm in longest diameter. The bulky mediastinal disease is defined as a mediastinal mass with a horizontal tumor diameter ≥1/3rd the thoracic diameter. EuroNet study protocol utilizes nodal volume ≥200 mL as measured on CT scan to define bulky disease

Table 2 Disease risk assignment by various pediatric Hodgkin lymphoma study groups [24]

Group	Risk	IA	IB	IIA	IIB	IIIA	IIIB	IVA	IVB
Children's Oncology Group (COG)	LR								
	IR	E X		E X					
	HR								
EuroNet-PHL-C1	TG1-LR								
	TG2-IR	E RF	E RF	E RF					
	TG3-HR				E	E			
EuroNet-PHL-C2	TL1-LR								
	TL2-IR	E RF	E RF	E RF					
	TL3-HR				E	E			

LR low risk, *IR* intermediate risk, *HR* high risk, *TG* treatment group, *TL* treatment level, *E* extranodal involvement, *RF* risk factors defined as ESR ≥30 mm/h and/or ≥200 mL volume in nodal or mediastinal mass

5 Principles of Management

Treatment of cHL has evolved over the decades from single modality approaches utilizing high-dose radiation and multi-agent chemotherapy to combined modality treatment incorporating chemo-radiotherapy. The burden of late effects of treatment in childhood HL survivors led to successive trials employing strategies to curtail therapy. Risk-adapted, gender-based, response-based protocols have a common aim of tailoring therapy maintaining excellent cure rates while minimizing toxicity.

6 Medical Management

The frontline treatment of cHL utilizes chemotherapy and radiotherapy.

6.1 Chemotherapy

Current multidrug regimens incorporate non-cross-resistant drugs with different mechanisms of action and non-overlapping toxicities. Initial regimens like MOPP had alkylating agents like mechlorethamine with higher leukemogenicity which led to its substitution with cyclophosphamide and development of COPP. But the permanent gonadal toxicity due to gonadotoxic alkylating drug, procarbazine led the way to the development of ABVD and non-alkylating agent-based regimens like VAMP and OEPA [25]. ABVD or derived hybrid combinations are used in many countries for low-risk diseases with the addition of other agents to intensify therapy for intermediate and high-risk diseases, but cardiopulmonary toxicity related to the use of anthracyclines and bleomycin is a potential concern. Chemotherapy regimens used in German DAL-GPOH-HD studies have evolved from OPPA/COPP to the OEPA/COPDac regimens used in EuroNet-PHL trials replacing procarbazine with etoposide and dacarbazine with reduced leukemogenicity and gonadotoxicity [26].

6.2 Radiotherapy (RT)

RT in the treatment of HL has been employed either singly or in combination with chemotherapy.

The use of radiotherapy in HL has evolved from the standard mantle field to involved field radiotherapy (IFRT) and involved site radiotherapy (ISRT), more so with the current combined modality approach. This together with modern imaging and delivery techniques for better conformal dosing has significantly contributed to reducing end-organ toxicity and sequelae.

The risk-adapted approach has helped in the delivery of graded intensity of RT across risk groups without compromising outcomes. The sites of delivery of RT are also variable across groups ranging from irradiating all initially involved nodal regions to only those with baseline bulky disease or poor response to initial chemotherapy.

Recent trials have shown that interim response assessment incorporating functional imaging in addition to anatomic considerations is a better and more sensitive tool in selecting patients for the avoidance of RT. Rapid early responders or those with adequate response could select patients in whom RT was avoided without compromising outcomes (details of trials in the response assessment section below). These trials have also shown that such a response-based strategy requires an intensive chemotherapy backbone.

7 Monitoring According to Risk Stratification

7.1 Response Assessment

Contemporary trials use response assessment after a few cycles of chemotherapy to define treatment duration and the need for radiation. Definitions for response assessment are variable across different protocols and have utilized CT scans for size reductions and/or functional imaging to assess activity by FDG-PET or Gallium scans.

7.1.1 Early Response Assessment (ERA)

Table 3 lists some of the trials that have used ERA for therapy titration.

Various regimens used for the treatment of HL are detailed in Table 4 (low-risk HL), Table 5 (intermediate-risk HL), and Table 6 (high-risk HL).

If there is persistent PET-positive disease at the end of the prescribed regimen or progression of the disease, a histological diagnosis is needed to confirm the presence of HL. Seldom a progressive disease or refractory disease is actually an infection like tuberculosis.

Table 3 Response assessment and therapy modification as per various Hodgkin's Lymphoma Study Groups

8 Nodular Lymphocyte-Predominant HL (NLPHL)

NLPHL has traditionally been included in the HL trials, though now they are separately studied due to their different clinico-immunophenotyping characteristics and behavior with excellent outcomes in limited disease warranting an approach different from cHL.

- NLPHL comprises 5–8% of childhood HL, with a higher proportion of prepubertal patients with significant male preponderance compared to cHL [35].
- A more indolent disease with a higher proportion of low-stage disease, mostly presenting as localized adenopathy in the neck. Mediastinal involvement is rare. Non-contiguous lymph node involvement can be observed in higher disease stages [36].
- Late and multiple relapses occur.
- There is an increased risk of transformation to NHL in up to 5–12% of cases [37].
- Histologically, there is effacement of lymph-node architecture with nodular lymphocyte infiltrates with scatted L&H cells or popcorn cells that express CD45, CD20, CD79a, and other normal B-cell antigens and are negative for CD15 and CD30. L&H cells are also EBV-negative [38].
- Given the favorable outcomes in those with a limited disease where major events are due to side effects of therapy, this less intensive strategy is implemented in contemporary treatment protocols. Completely resectioned stage IA can be observed alone and unresected stage IA/IIA can be treated with less intense chemo with RT only for those with poor response. Table 7 summarizes the options available.

Higher stages of the disease have better outcomes when treated on cHL regimens. A retrospective evaluation of treatment outcomes in advanced NLPHL from the UK and France which incorporated rituximab into multi-agent chemotherapy showed reasonable outcomes [42]. There are not many published studies from India, except the report from Tata Memorial Hospital which showed favorable outcomes despite unfavorable presentations in a heterogeneously treated cohort [43].

9 Management of Relapsed and Refractory HL

Relapse in HL has a realistic chance of cure prognostic factors including time to first relapse (most important), inadequate response to initial second-line treatment, stage at relapse, extra-nodal relapse, and a number of relapses. All relapses should be confirmed by biopsy and should be restaged using PET-CT. There is no survival benefit in routine surveillance by imaging in HL.

Treatment options are presented in Table 8.

Table 8 Salvage therapy options for relapsed Hodgkin lymphoma

Chemotherapy	Recommended second-line therapy, with the choice of drugs and schedule decided by previous therapy and initial response to these agents. Various regimens used include • ICE (ifosfamide, carboplatin, and etoposide) [44] • IEP/ABVD (ifosfamide, etoposide, prednisone/doxorubicin, bleomycin, vinblastine, dacarbazine) [45] • Ifosfamide and vinorelbine with or without bortezomib [46] • IGEV (ifosfamide, gemcitabine, vinorelbine) [47] • GDP (gemcitabine, dexamethasone, cisplatin) [48] • MINE (mitoxantrone, ifosfamide, vinorelbine, etoposide) [49] • Bendamustine [50]
Targeted therapy	Targeted therapy available includes • Rituximab either alone or combined with chemotherapy in CD20-positive relapses [51] • Brentuximab vedontin (Bv), anti-CD30 antibody linked to cytotoxic monomethyl auristatin-E (MMAE)
Checkpoint inhibitor therapy	These block the interaction between programmed death-1 (PD-1) and its ligands. Anti-PD-1 antibodies include: • Nivolumab (objective response: 87%) • Pembrolizumab (objective response rate of 65%)
Hematopoietic stem cell transplantation (HSCT)	Patients with refractory/early relapse, multiple relapses, and prior treatment with intensive chemo-radiotherapy respond poorly to conventional salvage therapy and have better remissions with myeloablative therapy followed by HSCT. Several studies report survival rates ranging from 30% to 60% [52–54]. Refractory/early relapse and PET positivity prior to transplant are risk factors for failure. Auto-SCT (mostly following BEAM [BCNU, etoposide, cytarabine, melphalan] conditioning) is the first choice in most centers. Reduced intensity conditioning (RIC) utilizing fludarabine or low-dose total body irradiation followed by allogenic-SCT is indicated if: • Relapse within 6 months of a prior autologous HSCT • Chemo-refractory disease (PET positivity after initial chemotherapy) • Bone marrow involvement at relapse
Radiotherapy	In sites not previously irradiated, RT can be used to enhance local control In sites not responsive to salvage therapy RT may be administered prior to HSCT
Novel agents	Novel agents under investigation include • Adoptive immunotherapy—autologous cytotoxic T lymphocytes (CTLs) against EBV antigens in cHL associated with EBV • Epigenetic therapies, such as the histone de-acetylase (HDAC) inhibitors like panobinostat

10 Late Effects

Late effects have their own significance in HL. Even though 5-year survival rates in HL are in excess of 90%, it steadily declines in the later years both due to relapse and late effects. Both chemotherapy (especially alkylating agents, anthracyclines, and bleomycin) and radiotherapy significantly, impair quality of life. The successive trials have adopted risk, gender, and response-based strategies to refine and tailor therapy to avoid many of these late effects. The following sections present the main late effects seen in HL survivors.

10.1 Cardiac Toxicity

Cardiac toxicity is mainly caused by anthracyclines and radiation exposure to the heart [55, 56].

Anthracycline-induced toxicity can manifest as subclinical left ventricular dysfunction, cardiomyopathy, or congestive heart failure.

Radiation-induced damage can lead to subclinical left ventricular dysfunction cardiomyopathy, pericarditis, heart valve dysfunction, conduction disorders, coronary, carotid, subclavian vascular disease, and myocardial infarction.

Strategies employed in the prevention of anthracycline cardiotoxicity include

- decrease cumulative anthracycline exposure
- use of analogs with less cardiotoxicity
- use of liposomal doxorubicin
- use of cardioprotectants like dexrazoxane
- drugs like angiotensin-converting enzyme inhibitors and beta blockers have only a transient effect
- pharmacogenomic led dosing
- risk factor (obesity, hypertension, diabetes, hyperlipidemia) prevention and treatment
- lifestyle modifications

10.2 Pulmonary Toxicity

Radiation, bleomycin, and HSCT contribute to pulmonary toxicity [57].

Radiation leads to pulmonary fibrosis, interstitial pneumonitis restrictive lung disease, and obstructive lung disease.

Bleomycin can cause interstitial pneumonitis pulmonary fibrosis ARDS and rarely pulmonary veno-occlusive disease. Patients who undergo HSCT in the relapse setting are at risk of bronchiolitis obliterans organizing pneumonia (BOOP), restrictive lung disease, and obstructive lung disease.

10.3 Thyroid Abnormalities

These include the following and are radiation-induced [58].

Radiation exposure leads to thyroid disorders and can manifest as hypo or hyperthyroidism. Risk factors include increasing radiation dose, female sex, and older age at diagnosis. The Childhood Cancer Survivor Study reported a 20-year actuarial risk of 30% in survivors treated with 35–44.9 Gy and 50% at doses ≥45 Gy. Develops most often in the first 5 years after treatment but can be seen up to 20 years. Annual TSH level monitoring is recommended if elevated and lifelong replacement therapy might be required.

Hyperthyroidism is seldom seen at high doses of radiation exposure.

Patients might also develop thyroid nodules. High radiation exposure and female sex are risk factors. Persistent and enlarged nodules require USG and periodic FNAC. The risk of thyroid cancer is 18-fold as compared to the general population.

10.4 Gonadal Toxicity

Alkylating agents predispose to gonadal toxicity. In males, high incidence of testicular dysfunction in alkylating agents, especially procarbazine-based regimens leading to its substitution with other agents (etoposide and dacarbazine in GPOH trials). Azoospermia is the main effect of preserved hormonal function. Hence sperm cryopreservation is to be discussed with post-pubertal boys before therapy initiation.

In females, if pelvic radiation is required ovaries can be transposed away from the radiation field premature menopause rates approach 3.8% for those who received pelvic radiation and alkylating agents.

10.5 Subsequent Neoplasms (SMN)

Fifteen-year cumulative incidence of secondary acute myeloid leukemia was 1% in DAL-HD studies when procarbazine was the alkylating drug. Drugs like etoposide and cyclophosphamide are also associated with sAML mostly seen in the first 7 years after therapy, but most of the newer regimens use doses below the leukemogenic threshold.

Risk for NHL is also increased with an estimated 20-year cumulative incidence of 1.5% [59].

The cumulative risk for the DAL/GPOH-HD study patients has been 5.7% after 20 years and increased to 11% after 22 years. The OS has been 94% after 20 years and dropped to 87% after 24 years.

In the study by the American Late Effects Study Group (LESG), the rate of secondary tumors increased steeply between 20 and 30 years. After 30 years the rate of secondary malignant tumors approached 25% mainly contributed by secondary solid tumors (SST) [59]. The main culprit for the development of SST is radiation therapy, and subsequently, modification of fields and doses have been attempted to reduce this late effect. However, one recent study indicated that a reduction in RT dose from 36–44 to 15–25 Gy may not significantly decrease the risk of second tumors.

10.6 Growth and Development

Growth retardation was seen more with previous regimens, which delivered high-dose axial skeleton radiation. The newer techniques employing lower doses and IFRT have significantly reduced this problem. Hypothyroidism may contribute to this late effect post-RT. Obesity and metabolic syndrome are concerns that have been recently noted to be on an increase in survivors.

11 Treatment Algorithms Used in Tata Memorial Hospital (TMH)

Step 1. Biopsy-proven treatment naïve cHL is staged using PET-CT

Step 2. Risk stratification is done as per Table 9

Step 3. The treatment algorithm is presented in Fig. 1

Table 9 Tata Memorial Hospital risk assignment strategy for classical Hodgkin lymphoma

Group	Risk	IA	IB	IIA	IIB	IIIA	IIIB	IVA	IVB
TMH	LR								
	IR	X	X	X E					
	HR				E X	E X			

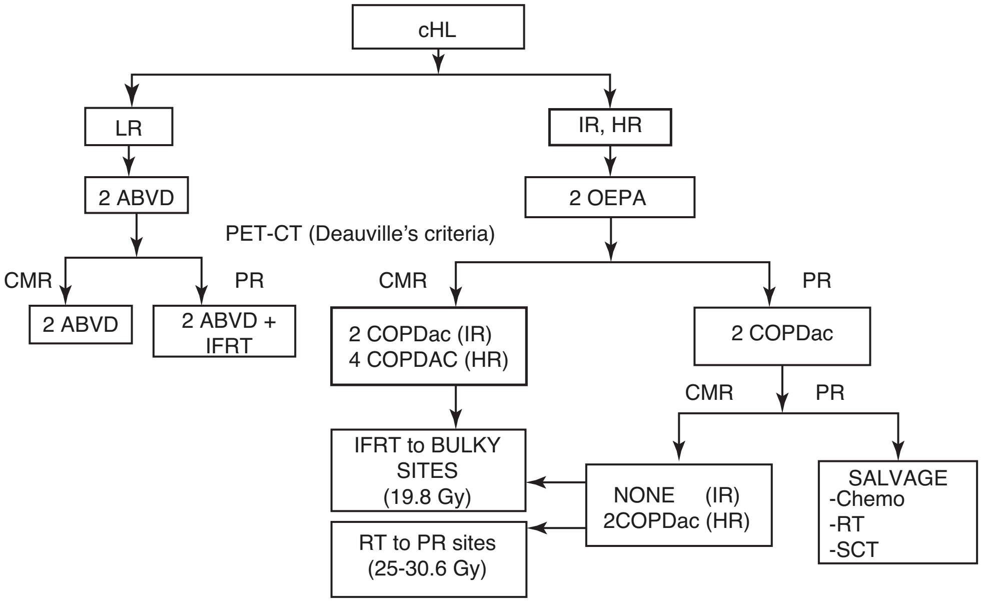

Fig. 1 In India, HL has conventionally been treated on a less intensive protocol utilizing ABVD and IFRT across all stages, with recent few protocols utilizing response-based RT across all stages. The only randomized controlled trial from India comparing combined modality treatment vs chemotherapy alone based on response assessment at the end of chemotherapy showed that consolidation radiation in those achieving complete response improved 8-year EFS (97% vs 53%, *p*-0.02) and OS (100% vs 89%, *p*-0.04) [60]. Intensifying primary chemotherapy has been shown to better select patients in whom RT can be avoided if rapid early response is obtained. The decision of continued application of RT to baseline bulky sites even in CMR on ERA despite being on an intensive chemotherapy backbone was taken in the institute considering the limited salvage options available to the population catered to. Even though relapse in HL provides a realistic chance of cure, brentuximab, nivolumab, and hematopoietic transplantation are not feasible options in the majority. A randomized controlled trial addressing the renunciation of RT even to bulky sites based on earl response assessment is being contemplated in a multi-centric fashion to allow solid evidence for the same

RAEBt	Refractory anemia with excess of blasts in transformation
RC	Refractory cytopenia
TAM	Transient abnormal myelopoiesis
UD	Unrelated donor

1 Introduction

Myeloproliferative neoplasm [MPN]/Myelodysplastic syndrome (MDS) overlap syndrome are disorders that have concurrent proliferative as well as dysplastic changes. MDS is characterized by anemia, leucopenia and thrombocytopenia in peripheral blood, dysplasia of various cell lineages in bone marrow, genetic anomalies and a high risk of progression to leukemia [1]. Clonal expansion of one or more hematopoietic cell lineages in the bone marrow, extramedullary infiltration in liver and spleen, and constitutional symptoms define MPN. There are various differences between adult and pediatric MDS, mainly in their clinical presentation and the cytogenetic abnormality associated with it. World Health Organization (WHO) 2003 and 2008 classification for pediatric MDS comprises three major diagnostic categories, as depicted below [2, 3].

1. Myelodysplastic/myeloproliferative disorders includes juvenile myelomonocytic leukemia (JMML), secondary chronic myelomonocytic leukemia (CMML) and *BCR::ABL1* negative chronic myeloid leukemia (Ph− CML)
2. Myeloid leukemia of Down syndrome (DS): includes transient abnormal myelopoiesis (TAM) and AML in children with DS
3. MDS includes the subtypes: refractory cytopenia (RC) with <2% blasts in PB and <5% blasts in BM, refractory anemia with excess blasts (RAEB) presents with 2–19% blasts in PB and 5–19% blasts in BM, and RAEB in transformation (RAEB-t) in children present with 20–29% blasts in PB or BM.

2 Incidence and Epidemiology in India and Globally

The incidence of pediatric MDS is lesser than 5% of all hematological malignancies [3]. Compared to adult MDS, the annual estimated incidence reported in childhood MDS is 0.5–4 per million and is typically detected in males under the age of 8; however, it can be diagnosed between the ages of 6 and 8 years, but with a male predominance. However, JMML (juvenile myelomonocytic leukemia) is commonly diagnosed in children with a median age presentation of 2 years. Since pediatric MDS is rare and difficult to diagnose, epidemiological data for pediatric MDS is limited. Several case series of pediatric MDS have been reported [4–12]. Sasake et al. [4] retrospectively analyzed 189 MDS patients less than 16 years old from 62 centers in Japan over 7 years. Tilak et al. [13] from northern India reported 19 cases of pediatric MDS with ages ranging from 3.5 to 16 years.

3 Clinical Presentation

Morphology, cytogenetics and prognosis differ significantly in adult and pediatric MDS. Anemia, bleeding and infection are the most prevalent symptoms in adult MDS patients, while fever secondary to neutropenia and bleeding due to thrombocytopenia are prominent in juvenile MDS patients. Constitutional and genetic disorders are strongly associated in 50% of MDS patients, as shown in Table 1; hence, screening for syndromic features like short stature, microcephaly, etc. is also very important in children.

Table 1 Predisposing conditions for childhood MDS [1]

Constitutional conditions
Congenital bone marrow failure
• Fanconi anemia
• Kostmann syndrome
• Shwachman–Diamond syndrome
• Blackfan–Diamond anemia
Trisomy 8 syndrome
Familial MDS (at least one first-degree relative with MDS/AML)
Associated conditions
• Prior chemotherapy/radiation, aplastic anemia

4 Evaluation and Work-Up Including Risk Stratification

4.1 Juvenile Myelomonocytic Leukemia (JMML) and Other Myelodysplastic/Myeloproliferative Disorders

Majority (>95%) of JMML cases are usually detected before the age of 4 with an annual incidence of roughly 4 per million. Currently used diagnostic criteria have been published [14, 15] (Table 2). Absolute peripheral blood monocytosis ($>1 \times 10^9$/L), presence of <20% blasts in peripheral blood or bone marrow, hepatosplenomegaly and absence of Philadelphia chromosome (*BCR::ABL1* fusion) are mandatory. JMML patients may present with bleeding, cough, pallor, fever, infection, poor weight gain, rash, leukocytosis, anemia, thrombocytopenia and elevated HbF. A bone marrow aspiration is required to rule out acute myelomonocytic leukemia, AML M4. Granulocytic cells are predominantly found at all stages of maturation with a hypercellular marrow. Monosomy 7 is seen in 25% of cases, random cytogenetic aberrations in 10% cases and 65% cases show a normal karyotype [15, 16]. Early and accurate diagnosis plays an important role in decision of therapy including stem cell transplant.

The newer diagnostic guideline for JMML recommends and incorporates molecular testing as depicted below in Table 3.

Table 2 Diagnostic guidelines for JMML [14, 15]

Suggestive clinical features	Hepatosplenomegaly
	Lymphadenopathy
	Pallor
	Skin rash
Laboratory criteria	No Ph chromosome, no BCR:ABL1 fusion
Minimal criteria (All 3 must be fulfilled)	PB monocyte count $>1 \times 10^9$/L
	Bone marrow blast count <20%[a]
Criteria for definite diagnosis (At least 2 must be fulfilled)	Hemoglobin F increased for age
	Myeloid precursors in blood smear
	White cell count $>10 \times 10^9$/L
	Clonal abnormality
	GM-CSF hypersensitivity of myeloid progenitors

[a] BM blasts may occasionally be 20–30% in an otherwise typical JMML.

Table 3 Latest diagnostic guidelines for JMML 2016 revision to World Health Organization Classification

Clinical and hematologic features (All are needed)	Absence of the BCR::ABL1 fusion
	$>1 \times 10^9$/L circulating monocytes
	<20% blasts in the peripheral blood and bone marrow
	Splenomegaly
Genetic studies (Any 1 is needed)	Somatic mutation in KRAS, NRAS, or PTPN11
	Clinical diagnosis of NF1 or NF1 gene mutation
	Germline CBL mutation and LOH of CBL
Other features if genetic testing not available (Along with clinical and hematological features)	Monosomy 7 or other chromosomal abnormality OR
	At least 2 of the below
	– Circulating myeloid or erythroid precursors
	– Increased hemoglobin F for age
	– Hyperphosphorylation of STAT5
	– GM-CSF hypersensitivity

CMML is included in the categorization; however, it is used only for cases that occur as a result of previous chemotherapy. In children, BCR::ABL1-negative chronic myeloid leukemia, included in the group of myelodysplastic/myeloproliferative disorders, is exceedingly rare, and presumably, the majority of cases are JMML.

Neurofibromatosis type I (NF-1) and Noonan syndrome (NS) are inherited diseases susceptible to develop JMML. Neurofibromatosis is found in about 14% of JMML cases with NF1 gene mutation in 30% of cases [17]. Children with Noonan syndrome (NS) are at very high risk of developing JMML or a myeloproliferative disorder (MPD). Mutations like CBL, KRAS, NRAS, NF1 and PTPN11 are present in about three-fourth of cases of JMML, while the remaining one-fourth of cases probably harbor unidentified mutated genes [18]. It is of paramount importance to define whether these mutations are somatic or germline as that determines the therapy.

4.2 Myeloid Leukemia of Down Syndrome (ML-DS)

Presence of constitutional trisomy 21 in patients with Down syndrome (DS) increases the risk of developing ML-DS by 150 folds. Acute leukemia is preceded by transient abnormal myelopoiesis (TAM), a neonatal clonal preleukemic syndrome that is unique to Down syndrome [19, 20].

4.3 Transient Abnormal Myelopoiesis (TAM)

TAM affects 4% to 10% of newborns with Down syndrome. It normally starts during fetal and neonatal life and disappears in 2–14 weeks, although 20% to 30% of cases advance to acute megakaryoblastic leukemia (AMKL) in 1–3 years. Blasts are morphologically and immunophenotypically similar to megakaryocytic lineage. Early mortality is seen in 17% of TAM patients due to leukocytosis, elevated bilirubin and liver enzymes [21].

GATA1 mutations and JAK-STAT pathway alterations are seen in both TAM and myeloid leukemia associated with Down syndrome, with more mutations in myeloid leukemia patients.

4.4 Refractory Cytopenia (RC)

Among the various subtypes of MDS, RC is the most common subtype accounting for approximately half of all MDS cases [15]. It is characterized by less than 5% blasts in BM, less than 2% blasts in PB and dysplasia in more than one lineage. A trephine biopsy is compulsory to differentiate between hypoplastic MDS from aplastic anemia (AA). The biopsy in hypoplastic MDS shows sparse granulopoietic cells which are scattered, islands of immature erythropoiesis with a patchy appearance and in most cases, decreased megakaryopoiesis or micromegakaryocytes [22]. Detection of monosomy 7, by conventional karyotyping, indicates poor prognosis. The usual time to progression for children, with monosomy 7 with RC to advanced MDS, is less than 2 years [23].

4.5 Advanced Pediatric MDS

The morphology and blast count in the BM is used to classify advanced pediatric MDS. Advanced pediatric MDS is divided into two groups by the WHO: (1) RAEB-1 (5–10% blasts) or RAEB-2 (11–19% blasts) and (2) RAEB-t (20–29% blasts). Morphology and immunohistochemical features of pediatric RAEB and adult are similar. However, blood counts remain stable in children for a long time. Transformation from MDS to AML occurs in 30% of pediatric MDS within 2 years of diagnosis [24, 25].

The most prevalent chromosomal aberration occurring in 30% of pediatric MDS is monosomy 7 conferring poor prognosis. These patients have a dismal outcome with standard therapy irrespective of the number of blasts in the BM. Abnormal karyotype has been found in 30–50% of pediatric MDS, and most of them show numerical abnormalities. Only 10% show structural abnormalities [26].

4.6 Principles of Management of MDS

Allogeneic stem cell transplant has remained the most definitive option for treatment of MDS and the majority of JMML as it is a clonal disorder of hematopoietic stem cells. The therapy has evolved over time and is derived from adult MDS patients. Unlike adults, in children, the aim of therapy is curative rather than palliative. Modern treatment using farnesyl transferase inhibitors, antiangiogenic agents and methylation inhibitors used in adults has not shown benefit in pediatric age group. In the past, treatment was done using low-dose cytotoxic agents or differentiating agents; however, the outcomes with the above were dismal [27–29].

4.7 Refractory Cytopenia (RC)

The policy of wait and watch can be done only in children with refractory cytopenia (RC) who do not carry monosomy 7 or a complex karyotype and are neither transfusion dependent nor endangered by low neutrophil count. In such patients, periodic blood examination and bone marrow testing as indicated or yearly would suffice. In case of progressive disease, such children can then be referred to the transplant unit [23]. In those who are transfusion dependent or neutropenic, a transplant with a matched sibling or unrelated donor should be offered at the earliest with a probability of EFS being around 75% at 3 years. For patients with RC with no cytogenetic abnormality, conditioning regimens with reduced intensity have shown similar outcomes [30].

4.8 Advanced Primary MDS (RAEB/RAEB-t)

Cytoreductive therapy before proceeding to stem cell transplant is controversial. Few groups have included RAEB and RAEB-t as AML and have given therapy like AML. In such a group of patients, the expected results have been a remission rate of <60% with 5-year survival of <30% with plenty of relapses. Data from EWOG-MDS indicate that pretransplant chemotherapy did not improve survival, and the probability of survival after transplant was almost 50%. The outcomes were again not influenced by blast percentage in the bone marrow at the time of stem cell transplantation [31].

Patients can be transplanted either with a matched sibling, unrelated donor or haploidentical with almost similar outcomes [32–34]. Most of the study groups have used busulfan-based conditioning regimens with graft versus host disease prophylaxis being cyclosporine [35]. In the EWOG-MDS studies, the event-free survival at 5 years is 60% and approximately 40% for patients given stem cells from an MSD or an UD [31]. With the improvement in techniques of depleted grafts, it is possible, in future, that haploidentical transplants could also be a possibility, especially in scenarios where a match is not available.

4.9 Treatment of Secondary MDS

The probability of cure with allogeneic stem cell transplant in this group remains in the range of 20–30% overall survival in a few reported series [36]. The Children's Cancer Group (CCG) has reported better outcomes for intensive chemotherapy followed by stem cell transplantation compared to standard chemotherapy and transplant [37].

4.10 Principles of Management of JMML

JMML is a heterogeneous myeloproliferative disorder. It was previously treated like a MDS or leukemia; however, outcomes after therapy with these modalities have resulted in dismal outcomes. Cis-retinoic acid has shown durable remission in single-institution case series; however, there is no documented long-term survival with this single agent [38]. The most definitive therapy is stem cell transplant; however, in the era of molecular testing, few subsets of patients have been identified that do not mandate a stem cell transplant as described below [39].

4.11 Treatment of CBL Mutation

Patients carrying CBL mutation (≈15% of all cases) have congenital anomalies similar with those observed in neurofibromatosis 1. Children with germline CBL mutations develop JMML because of higher risk of having a loss of heterozygosity (LOH) for the CBL locus in progenitor stem cells. Majority of the children have self-resolving disease with only a few having a stormy clinical course. They often require only a low dose of short course of chemotherapy. Stem cell transplant is indicated only if the child progresses on wait and watch policy [39].

4.12 Treatment of Germline Mutation of KRAS/NRAS

In the EWOG MDS study, it was observed that children with germline RAS mutation with normal HbF levels and platelet counts had good outcomes without transplant; hence, these patients can be observed alone and planned for transplant if they progress.

4.13 Treatment of Somatic Mutation of KRAS/NRAS/PTPN11 and NF-1

Allogenic stem cell transplant is the only curative option for children with JMML associated with somatic mutations of KRAS/NRAS, NF-1 and PTPN11.

4.14 Principles of Management of TAM in Downs Syndrome

Majority of the neonates with TAM do not need any form of therapy and usually self-resolve over time [40]. Neonates with symptoms which are life-threatening like *hydrops fetalis*, hyperleukocytosis (WBC >100 × 10^9/L), liver dysfunction with DIC picture, kidney dysfunction or cardiac manifestations may benefit from lower doses of chemotherapy. The mortality rate reported for such symptomatic neonates is as high as 20% [41]. These children are extremely sensitive to cytarabine, and the recommended dose is 1 mg/kg for 3–12 days till symptom resolution.

A management algorithm for MDS is presented in Fig. 1, and a management algorithm for JMML is presented in Fig. 2.

4.15 Prognosis with Current Treatment

4.15.1 MDS

Outcomes with stem cell transplant in these patients have been reported between 50% and 73% in the literature. The key prognostic element is time to transplant, and outcomes with transplant posttransformation to AML are poor [31–35].

4.15.2 JMML

Prognosis with stem cell transplant in patients with JMML as reported by EWOG-MDS trial is 52% EFS and OS of 64% at 5 years [42]. The important prognostic factors in the study were age at transplant, gender and presence of cytogenetic anomalies. Age less than 2 years and male gender had superior outcomes. In the study, del (7q) had better outcomes compared to normal/other cytogenetic anomalies.

4.16 Management of Recurrent Disease in Patients with MDS

Relapses following transplant in children with MDS is associated with a dismal outcomes. Salvage with donor lymphocyte infusions has occasionally been reported. Similar to most transplants in benign hematology, children with early relapse, detected by loss of chimerism or mixed chimerism, may need early withdrawal of the graft versus host disease prophylaxis and donor lymphocyte infusion, but they are at high risk of Graft versus host disease [43].

4.17 Management of Recurrent Disease in Patients with JMML

Repeat allogeneic stem cell transplant with same or alternate donor in patients with relapsed JMML has good outcomes. In the EWOG trial, 68 patients relapsed, out of which 26 had undergone a second transplant. The probability of 5-year disease-free survival in these patients was 32% [41].

5 How We Do It at TMC

In TMC, any child with suspected MDS/JMML is worked up as shown in Table 4.

Table 4 Work-up of child with suspected MDS/JMML

Evaluation

- Detailed history and clinical examination
- Complete blood count with manual differential counts
- Organ function testing
- Hemoglobin F levels
- Bone marrow evaluation with biopsy (aspirate for morphology, cytogenetics and molecular testing)
- Cytogenetics is processed for Monosomy 5/7, Ph chromosome and conventional karyotyping
- Testing for chromosomal fragility is done in suspicion of Fanconi anemia
- Molecular testing includes detection of KRAS, NRAS, PTPN11 and CBL mutation
- HLA typing of siblings and parents
- In a matched sibling, cytogenetic and molecular testing is done to rule out constitutional syndromes prior to transplant

Treatment

- To counsel for allogenic stem cell transplant
- Wait and watch for patients with refractory cytopenia (nontransfusion-dependent/nonneutropenic) and JMML with CBL mutation and germline KRAS/NRAS/PTPN mutation

Hematopoietic Stem Cell Transplantation

Avinash Bonda and Navin Khattry

Abbreviations

ALL	Acute lymphoblastic leukemia
AML	Acute myeloid leukemia
BM	Bone marrow
CML	Chronic myeloid leukemia
GVHD	Graft versus host disease
HD	Hodgkin's disease
HSC	Hematopoietic stem cell
KDR	Kinase domain receptor
MDS	Myelodysplastic syndrome
NA	Nucleoside analog
NHL	Non-Hodgkin's lymphomas
TBI	Total body irradiation
TLI	Total lymphoid irradiation

1 Introduction

Hematopoietic stem cell transplantation refers to the infusion of pluripotent stem cells, usually derived from bone marrow, peripheral blood or umbilical cord. It may be autologous (the patient's own stem cells are used), allogeneic (from a donor) or syngeneic (from an identical twin).

Stem cells are a population of undifferentiated cells capable of indefinite self-renewal and generation of a functional progeny of highly specialized cells. Stem cells have variable proliferative properties and functions depending on their tissue compartment. Hematopoiesis is a continuous developmental process in which the hematopoietic stem cells (HSCs) produce the various blood lineages depending on specific cell fate variations [1]. The most primitive stem cells express the cell surface antigen CD34 and receptors for the early-acting hematopoietic growth factors: kinase domain receptor (KDR [flk-1]), vascular endothelial growth factor and the positive hematopoietic development regulators, c-kit and FLT-3 [2].

For the purpose of transplantation HSCs can be collected from bone marrow (BM) or peripheral blood. Hematopoietic reconstitution after BM ablation depends on the migration and "homing" of these intravenously transfused stem cells to the hematopoietic microenvironment in the BM niches of the recipient (Fig. 1). They form a small part of the transplant recipient's stem cell pool and divide slowly with limited expansion and reverting to a dormant state when mature compartments are fully reconstituted. However, despite adverse conditions in the host BM niches, the infused HSCs generate sufficient progenitors to repopulate the host hematopoietic system with mature cells (Fig. 2).

STEP 1 COLLECTION
STEP 2 PROCESSING
STEP 3 CRYOPRESERVATION
HIGH-DOSE CHEMOTHERAPY AND / OR RADIATION IS GIVEN TO THE PATIENT
STEM CELL INFUSION
ENGRAFTMENT

Stem cells are collected from the patient's peripheral blood

Stem cells are collected from the donor's peripheral blood or marrow

The stem cells are prepared for processing or preservation

In certain cases the donor stem cells are processed for freezing /or selection

Stem cells are preserved by freezing if the transplant is planned for a later date.

In certain cases where in the donor stem cells are collected ahead of the transplant cryopreservation is done.

Fig. 2 Outline of hematopoietic stem cell transplantation

2 Historical Aspects

After 50 years of hematopoietic stem-cell transplantation for cancer therapy, it has progressed from several complications to becoming a standard treatment for many hematological malignancies.

The era of hematopoietic stem cell transplantation began during the first atomic bomb explosions, by Leon Jacobson et al. in 1949 who showed that mice could be protected from the lethal effects of ionizing radiation on bone marrow by shielding their spleens with lead [3]. Jacobson further demonstrated a similar protective effect by shielding the femur. Lorenz and colleagues showed that protection against radiation could also be conferred by intravenous infusions of bone marrow [4]. Initially, it was thought that protection was affected by some "hormone" or "growth factor" in the spleen or bone marrow that stimulated hematological recovery [3, 5]. In the 1950s, Barnes and Loutit [6] and Main and Prehn [7] have shown that radiation protection was due to transplanted stem cells [6–10].

The fact that all hematopoietic stem cells arise from pluripotent stem cells led to widespread research into the potential for bone-marrow transplantation as a treatment for hematological malignancies, involving intensive irradiation and intravenous infusion of bone-marrow cells to protect the recipient from life threatening bone-marrow aplasia. The early studies were pioneered by E. Donnall Thomas and colleagues who began their human bone-marrow grafting program in 1955, and showed in 1957 that human hematopoietic stem-cell transplants were, for the most part, unsuccessful, with only one patient undergoing a transient engraftment [10]. The other patients died of progressive disease or allograft failure. Despite the poor results, these trials showed for the first time that when grafts were carefully screened before infusion (to remove fat and bone particles), relatively large amounts of bone marrow could be administered to human patients without serious side effects. In 1959, three landmark papers were published that described the transplantation of bone marrow into leukemia patients and into victims of radiation exposure [11–13].

The second half of the 1960s saw the development of high-dose conditioning regimens. These consisted of the maximally tolerated doses of TBI and/or chemotherapy (such as the alkylating agent cyclophosphamide), which not only served to kill cancer cells, but also suppressed the hosts' immune systems so that graft rejection could be prevented.

In the latter half of the 1980s, technologies were refined and alternative graft donors and sources were found. T-cell depletion [14] and pharmaceutical agents [15] were shown to minimize graft versus host disease (GVHD). Due to the fact that only around 35% of patients have HLA-matched siblings, the use of alternative donors began to include extended family members who share one HLA haplotype, and to unrelated HLA-matched and -mismatched donors. Alternative sources of stem cells, such as cord blood and peripheral blood have begun to be employed as potential graft sources.

In order to overcome the hurdle of age, recently developed less intensive hematopoietic stem-cell transplantation programs with reduced intensity conditioning, rely less (or not at all) on chemoradiation therapy and shift the burden of tumor-cell killing toward graft versus tumor effects [16]. These so called nonmyeloablative or mini-transplant approaches, have been translated directly from preclinical models into the clinic.

3 Indications for Hematopoietic Stem Cell Transplant (Table 1)

Table 1 Indications for hematopoietic stem cell transplant

Autologous transplantation
Cancers
Multiple myeloma
Non-Hodgkin's lymphoma
Hodgkin's disease
Acute myeloid leukemia
Neuroblastoma
Germ-cell tumors
Ewing sarcoma
Other diseases
Autoimmune disorders
Amyloidosis
Allogeneic transplantation
Cancers
Acute myeloid leukemia
Acute lymphoblastic leukemia
Chronic myeloid leukemia
Myelodysplastic syndromes
Myeloproliferative disorders
Non-Hodgkin's lymphoma
Hodgkin's disease
Chronic lymphocytic leukemia
Multiple myeloma
Juvenile chronic myeloid leukemia
Other diseases
Aplastic anemia
Paroxysmal nocturnal hemoglobinuria
Fanconi anemia
Blackfan–Diamond anemia
Thalassemia major
Sickle cell anemia
Severe combined immunodeficiency
Wiskott–Aldrich syndrome
Inborn errors of metabolism

4 Types of Hematopoietic Stem Cell Transplantation

The types of hematopoietic stem cell transplantation are as follows:

- Autologous transplants
- Allogeneic transplants
  - **Related donor**
    - Matched sibling donor
    - Haploidentical donor
    - Umbilical cord
  - **Unrelated donor**
    - Matched-unrelated donor
    - Single antigen mismatched donor
    - Umbilical cord
- Syngeneic transplants

The advantages and disadvantages of the types of transplantation are presented in Table 2.

Table 2 Advantages and disadvantages of types of transplants

Type of transplant	Advantages	Disadvantages
Allogeneic		
Sibling donor 10/10 HLA match or 9/10 match	Rapid identification of match (2 weeks) Lower rate of graft rejection (2–5%)	GVHD (25–45%) in a non-T deplete marrow graft The probability of a match with siblings is only 30%
Matched-unrelated donor	Broadens the donor availability (60–70% will have a potential match) Greater graft vs. tumor effect and hence better chance of progression-free survival	Longer duration to find a match (2–6 months) Higher graft failure risk (5–10%) Higher risk of GVHD (50–60%) Higher risk of nonrelapse mortality
Umbilical cord donor	Lesser degree of match can be used Much lower rate of GVHD despite one and two antigens mismatch (10–20%)	Limited dose (difficulty for a large recipient) Delayed engraftment Higher chances of graft failure (10%) No possibility of DLI for posttransplant relapse
Haploidentical-related donor	Almost all patients have a sibling or parent or both who can be a potential donor	Profound immunosuppression Higher infectious complications Higher risk of graft failure (10–15%)
Syngeneic		
Identical twin	Immunosuppression not required No GVHD	No GVT effect

5 Biological Principles of High-Dose Chemotherapy and Radiation

High-dose chemotherapy is required to “condition” or “prepare” patients prior to a transplant for eradicating the tumor and “creating space,” so that graft would home and then reconstitute the host immune system and accordingly named as conditioning or preparative regimen. This was accomplished by applying an empiric combination of total body irradiation (TBI) and cyclophosphamide [17]. In the later years, combination chemotherapy without TBI began [18]. The concept of “creating space” has gradually been replaced by a more diverse and complex, mechanisms involved in engraftment. Also, the idea of eradicating tumor cells with high-dose chemotherapy and replacing the patient’s immune system with that of the donor has been substituted by engraftment along with tumor killing facilitated by the conditioning regimen. After engraftment of the immune cells, a **graft versus tumor effect** is exerted against residual tumor cells to accomplish long-term freedom from progression. A wide range of combinations of drugs with synergistic antitumor activity with minimal risk for normal tissue toxicity are increasingly employed now in conditioning. These allow to improve the antileukemic effects and the immunosuppressive capability of the preparative regimen. Further, treatment intensity can be modulated in proportion to the effectiveness of immune-mediated tumor killing by the graft [19–21]. These approaches aim at optimizing patient safety and minimizing serious treatment-related adverse events while maximizing antitumor effects. The more recent introduction of nucleoside analog (NA) combinations in pretransplant conditioning provides both the intense immunosuppression necessary to facilitate engraftment and an improved antitumor effect by inducing DNA damage and inhibiting DNA repair. The various drugs used in hematopoietic stem cell transplant are as follows:

- **Autologous transplants**
  - MEL
  - VP-16
  - BCNU
  - Ara-C
  - Cyclophosphamide
  - Busulfan
  - Carboplatin
  - MAb
  - ThioTEPA
  - TBI
  - Gemcitabine
  - Treosulfan
  - Bortezomib
  - CCNU

- **Allogeneic transplants**
    Fludarabine
    Cyclophosphamide
    Busulfan
    TBI
    ATG
    MEL
    MAb
    VP-16
    ThioTEPA
    Ara-C
    BCNU
    Treosulfan
    Clofarabine
    Pentostatin
    TLI/TNI/TAI

6 Total Body Irradiation

Irradiation is used primarily as a form of systemic therapy utilizing high-energy photons and large fields to deliver total body irradiation (TBI). In addition, total lymphoid irradiation (TLI) and locoregional irradiation directed to areas of higher tumor burden have also been combined with chemotherapy in HCT conditioning regimens. A primary role of TBI is the eradication of malignant cells; however, it also provides a powerful means of immunosuppression to prevent graft rejection. TBI is often combined with chemotherapy in conditioning regimens and offers distinct advantages over chemotherapy. Unlike chemotherapy, delivery of radiation therapy to the tumor site is not dependent on blood supply or influenced by interpatient variability of drug absorption, metabolism, biodistribution, or clearance kinetics. Radiation therapy can reach potential sanctuary sites, such as the testes and central nervous system. Chemotherapy-resistant clones may still be sensitive to irradiation. Unlike in chemotherapy, the radiation dose can be preferentially distributed to areas of greatest tumor burden and restricted to critical normal organs. Typical TBI schedules deliver a total dose of 10 to 14 Gy at 1.2 Gy three times daily (TID), 2 Gy twice daily (BID) or 3 Gy once daily (QD). A variety of TBI schedules have been evaluated to reduce toxicities and improve relapse rates and the therapeutic index. Factors that are of radiobiologic importance include total dose, fraction schedule, fraction size, use of organ shielding and dose rate. The long-term complications of TBI include Endocrine and reproductive (gonadal) insufficiency, growth disorders (in childhood), hypothyroidism, lung fibrosis, cataract, secondary malignancies, irreversible alopecia, cardiomyopathy.

Indications for TBI are as follows:

Leukemias in adults and childhood:
- Acute lymphoblastic leukemia (ALL)
- Acute myeloid leukemia (AML)
- Chronic myeloid leukemia (CML)
- Myelodysplastic syndrome (MDS)

Optional indications
- Solid tumors in childhood:
    - Neuroblastomas
    - Ewing sarcomas
    - Plasmocytomas/multiple myelomas

7 Outcomes of HSCT (in Adults) in Various Diseases (Table 3)

Table 3 Outcomes of HSCT (in adults) in various diseases

Disease status	Role of HSCT
AML	HSCT is used as consolidation strategy in first CR for certain risk groups, for patients who are refractory to standard chemotherapy and at relapse. Allogeneic HSCT is not recommended for patients in first CR with good risk AML. However, in patients with acute promyelocytic leukemia not achieving a molecular response after frontline consolidation or after salvage treatment, an allogeneic HSCT is recommended. Patients in first CR with intermediate-risk and high-risk AML are candidates for HLA-identical sibling donor HSCT.
ALL	Adults with ALL with poor prognostic features, for example, t(9;22) or t(4;11), or failure of induction chemotherapy, are candidates for allogeneic HSCT from either an HLA-identical sibling or an unrelated donor. Patients with relapse are candidates for allogeneic HSCT from an HLA-identical sibling, an unrelated donor or other alternative donors such as cord blood or haploidentical donor.
MDS	Allogeneic HSCT is considered the treatment of choice for adult patients with myelodysplastic syndrome (MDS) or AML evolved from MDS and offers a good chance of long-term disease-free survival. Whether the transplant is done upfront or after a few initial courses of hypomethylating therapy depends on the baseline blast count. A pretransplant blast count of less than 5% is beneficial.
CML	HSCT remains the only curative treatment for CML. However with the advent of TKI therapy, the indications are few. Patients in the blast crisis at diagnosis should be referred for HSCT as soon as possible. While preparing for HSCT, initial therapy with TKI or intensive therapy ± TKI might be an option. HSCT should be performed as soon as possible after achieving the second chronic phase. Patients with ABL mutations that are resistant to the second-generation TKI may benefit from HCT.
NHL	Autologous HSCT is the standard therapy for patients with chemosensitive relapse of diffuse large B-cell lymphoma (DLBCL) [22]. Patients with refractory disease, early relapse—within 12 months, have a very poor prognosis. The role of CART cell therapy and bispecifics becomes important here.
Myeloma	Autologous HSCT is the standard of care for all the eligible patients who respond to first-line treatment. Age should be considered in light with the patient's general health and fitness. Tandem autologous HSCTs have been shown to be superior to one autologous HSCT, although the benefit of the second transplant seems to be restricted to patients not achieving CR or very good PR with the first transplant.
Hodgkin lymphoma	Autologous HSCT is the standard therapy for patients with Hodgkin's lymphoma (HL) in first chemosensitive relapse [23]. Refractory disease if responds to salvage therapy (chemotherapy, immunotherapy and brentuximab or a combination of these) might benefit from an autologous HSCT [24, 25]. Allogeneic HSCT has mainly been used as salvage therapy for multiply relapsed or refractory HL patients.

8 Outcomes of HSCT (in Children) in Various Diseases (Table 4)

Table 4 Outcomes of HSCT (in children) in various diseases

Disease status	Role of HSCT
AML	In pediatric AML, the role of allo-HSCT in CR1 remains for the high risk. Infant AML and children with FAB M0, M6 or M7 AML are indications for allogeneic HSCT. In children with relapsed AML, allogeneic HSCT is indicated either from a sibling or an unrelated donor.
ALL	The indication for HSCT in children with ALL in CR1 is limited to the subpopulation of the high-risk ALL with an estimated EFS of <50% especially groups like persistent minimal residual disease. ALL patients, who experience an early marrow relapse, are candidates for transplant with sibling or alternative donors as the outcomes are similar.
MDS	Allogeneic HSCT from a sibling donor or a well-matched-unrelated donor is the treatment of choice for children with primary MDS, including juvenile myelomonocytic leukemia and secondary AML.
Lymphomas	Patients who fail to respond to upfront therapy or those with chemo-sensitive relapsed diseases can achieve long-term disease-free survival after autologous HSCT. Allogeneic HSCT is beneficial in multiply relapsed refractory setting.
Solid tumors	Neuroblastoma (stage IV beyond the age of 1 year, or high-risk factors in lower stages) is still the only indication for which the benefit of high-dose therapy with autologous HSCT has been shown by randomized trials [26, 27]. Children and adolescents with solid tumors might undergo autologous HSCT after high-dose chemotherapy within clinical research trials, in the following situations: • Neuroblastoma (high risk, >CR1) • Ewing's sarcoma (high risk or >CR1) • Brain tumors: children with medulloblastoma and high-grade gliomas responsive to chemotherapy in an attempt to avoid or postpone radiotherapy. • Germ cell tumors: after a relapse or with progressive/refractory disease

9 Current Status of HSCT: Indian Perspective

The first bone-marrow transplantation in India was done in 1983 at Tata Memorial Hospital, Mumbai. There has been a steady rise in number of transplant centers in India over last few years. In India, the larger transplant centers are: Tata Memorial Hospital, Mumbai; Christian Medical College, Vellore; AIIMS, New Delhi; Apollo Cancer Hospital, Chennai; Army Hospital R&R, New Delhi; SGPGI, Lucknow; Cancer Institute (WIA), Chennai; Rajiv Gandhi Cancer Institute, New Delhi; PGIMER, Chandigarh. The average cost varies from Rs 6 to 15 lakhs per procedure depending on the type of transplant and the center.

Indian Stem Cell Transplant Registry (ISCTR) (Nov 2017) data reveal a definite increase in the total number of transplant centers reporting from 52 to 65, and total number of transplants also continue to increase by around 10% per year with 2016 seeing 1878 transplants reported to ISCTR.

Infections especially early bacterial infections are the major threat to success of any transplant program. Sixty-five transplant centers from 25 countries across Europe, Australia and Asia reported data on 655 GNR episodes and 704 pathogens in 591 patients. Unfortunately, half of these gram-negative bacteria were fluoroquinolone and non-carbapenem-resistant; 18.5% carbapenem-resistant and 35.2% multidrug-resistant [28]. Interestingly, total resistance rates were similar in community-acquired infections. Gram negative sepsis has been major cause of mortality and morbidity in India. Kamble et al. [29] reported data on 516 blood culture samples received from 74 patients from different sites. Sixty-three cultures were positive in 21 patients (12%). There is an urgent need to curb the emergence of MDR organisms in our country.

DONOR MOBILISATION AND RECRUITMENT
SCREENING AND CONSENTING

Fig. 3 Activities in a marrow donor registry program

Unrelated donor registries in India include DATRI and MDRI (marrow donor registry of India) (Fig. 3).

The MDRI is India's first NGO that maintains a computerized database of voluntary, unrelated stem cell donors and facilitates blood stem cell transplants for patients with life-threatening blood diseases. It recruits donors, maintains a registry of volunteer potential donors and initiates a search for HLA typed stem cell donors for a patient requiring a transplant anywhere across globe. This was the noble initiative of a Mumbai-based hematologist, Dr. Sunil Parekh, in 2008.

DATRI is another Indian marrow donor registry that was cofounded and run by Raghu Rajagopal, an entrepreneur in Chennai. The registry has partnered with a US high-resolution tissue-typing company called HistoGenetics, which has provided DATRI with financial support and carries out HLA typing for potential donors.

Part IV

Solid Tumors

Central Nervous System (CNS) Tumors

Aliasgar Moiyadi, Vikas Singh, Raees Tonse,
and Rakesh Jalali

Abbreviations

ATRT	Atypical teratoid/rhabdoid tumors
BBB	Blood–brain barrier
CNS	Central nervous system
CT	Computed tomography
DTI	Diffusion tractography imaging
EGFR	Epidermal growth factor receptor
ETMR	Embryonal tumor with multi-layered rosettes
GCT	Germ cell tumor
GTCS	Generalized tonic-clonic convulsion
IDH	Isocitrate dehydrogenase
IGRT	Image-guided radiation therapy
IMRT	Intensity-modulated radiation therapy
MB	Medulloblastoma
MRI	Magnetic resonance imaging
MRS	MR spectroscopy
PCNSL	Primary central nervous system lymphoma
PCV	Procarbazine, lomustine, and vincristine
PET	Positron emission tomography
PNET	Primitive neuro-ectodermal tumor
PT	Proton beam radiation therapy
PXA	Pleomorphic xanthoastrocytoma
SRS	Stereotactic radiosurgery SVZ sub-ventricular zone
VMAT	Volumetric modulated arc therapy
WBRT	Whole brain radiation therapy

1 Introduction

Central nervous system (CNS) tumors include a wide spectrum of tumors that vary with regard to age, location, histology, and clinical outcomes. Epidemiologic studies have shown a trend toward increasing incidence of brain tumors attributable to increased life expectancy, improved detection rates (with better and advanced imaging techniques), and more systematic documentation and reporting due to the introduction of cancer registries. The delicate and exquisitely eloquent nature of the brain and spinal cord poses a significant dilemma in treating these tumors (where oncological principles of radicality must be counter balanced against the need for function preservation). Recent advances in diagnostic imaging, intraoperative surgical adjuncts, radiotherapy techniques, and the introduction of newer systemic therapies have helped improve patient outcomes. Nonetheless optimizing treatment outcomes remains an ongoing challenge and area of intense research.

2 Epidemiology (Global and Indian Perspectives)

CNS tumors constitute approximately 2% of all malignancies. Though primary brain tumors account for about 2.8% of all cancer deaths, their adverse impact is disproportionately higher, in terms of years of life lost from cancer [1]. Brain tumors represent approximately 85–90% of all CNS tumors, of which, the age-adjusted average annual incidence rates vary among the population. In general, the incidence in males is more than in females. Glioma and meningioma are common primary tumors (age-adjusted average annual incidence rates of 6.45 and 5.55 per 100,000 population, respectively) [2]. The incidence of gliomas, germ cell tumors, and cysts is higher in men, whereas women have a higher incidence of meningioma. Spinal tumors account for 10–15% of

primary CNS tumors [3]. Most primary CNS spinal tumors are benign (in contrast to intracranial tumors) and are likely to have compressive rather than invasive features [4].

Brain metastases are the commonest brain tumors seen in adults (much less common in children), comprising over half of all brain tumors overall. Depending on the level of screening and general outcomes of other primary cancers in the region, the incidence of metastases can vary. Fifteen to thirty percent of patients with cancer develop cerebral metastasis [5]. The most common site of primary is the lung, breast, melanoma, colon, and kidney. Melanomas have the highest propensity for developing cerebral metastasis followed by lung and breast carcinomas. Up to 10–15% of cerebral metastases may yield no known primary in spite of extensive workup [6].

Brain tumors are the second most common form of malignancy (after leukemia) and a leading cause of cancer-related death in children. CNS tumors in children (0–18 years) differ from those of adults, particularly with regard to their location and histologic/molecular subtypes [7]; medulloblastomas and astrocytomas are more commonly encountered than other histologic subtypes. In children, the majority (70%) of tumors are infratentorial as compared to only 30% in adults. They are also responsible for 20% of malignant tumors diagnosed before the age of 15 [8].

Data from the Indian subcontinent are sparse due to a lack of cancer registries, and most published literature is institution based [9, 10]. Incidence of CNS tumors in India ranges from 5 to 10 per 100,000 population, and there has been an increasing trend in registrations at referral centers. At our own center, we have seen an exponential rise in registered cases over the last decade, the dip during the pandemic period (2020–21) notwithstanding (Fig. 1). In adults, the most common brain primary tumors are astrocytomas (38.7%) High-grade glioma (59.5%) is the most frequently diagnosed histologic sub type amongst astrocytomas. The median age of diagnosis of glial tumors was seen to be at least a decade earlier than reported in the Western population, which may be due to the lower life expectancy and a higher proportion of the young population in India [11]. Institutional studies report similar histological distribution of tumor types in adults as well as children as is the global trend [10, 12].

From an etiologic perspective, the heterogeneity of histologic diagnoses within CNS tumors indicates multiple probable causative mechanisms. CNS tumor incidence varies among different populations with certain ethnic groups like Jews having a higher propensity [13, 14]. Environmental factors may contribute to the increased incidence of tumors in certain regions [15, 16]. Multiple factors like medical history (and immunologic status), family history, and genetic factors have been reported to have a weak and inconsistent association with the risk of CNS tumor development. Host factors like rare genetic syndromes, a family history of CNS tumors, and congenital malformations are known to have the strongest association with the development of CNS tumors. Certain hereditary and congenital diseases with increased risk of CNS tumors [17] are neurofibromatosis [18], Tuberous scelorosis, Li–Fraumeni tumor syndrome [19], ataxia telangiectasia [20], Gorlin syndrome, and Turcot syndrome [21]. The loss of tumor suppressor genes like p53 seems to be a fundamental mechanism in the development of several CNS tumor types [22, 23]. Cytogenetic abnormalities like the loss/translocation of parts of chromosome 22 in familial meningioma and acoustic neuroma and gains on chromosome 7/loss on 9 in gliomas have been described [24–27].

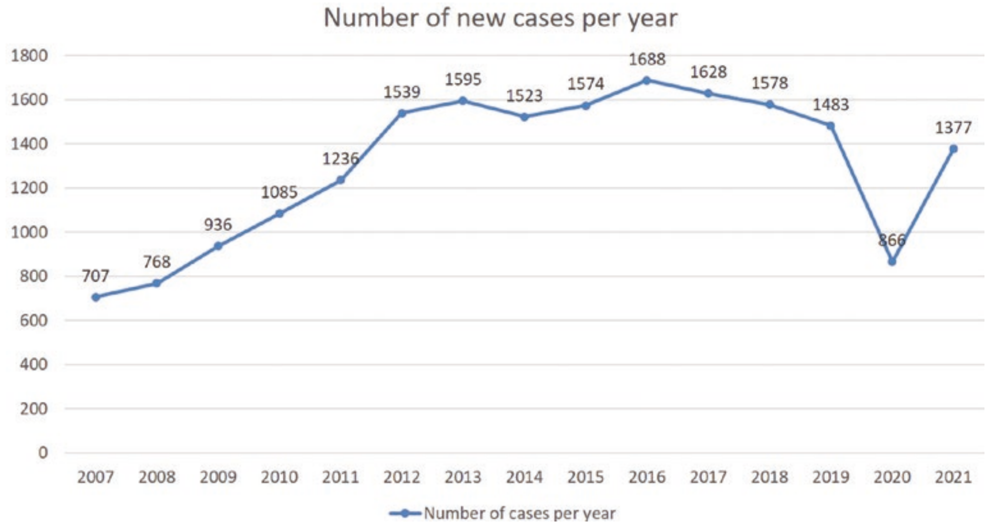

Fig. 1 Number of new case registrations in neuro-oncology, Tata Memorial Centre 2007–2017

A causal relationship between ionizing radiation and CNS tumors is well known. Published literature has shown that exposures in utero [28, 29], high-dose irradiation in childhood [30] and in adult life [31] increase the risk of CNS tumor. A possible association between mobile (cellular) telephone use and CNS tumor risk remains highly debatable. However, extensive research on the association between mobile phone usage and CNS tumor development has not shown a substantially increased risk [32, 33]. Associations between diet, occupation, smoking, and immunocompromised states and CNS tumors in humans have been postulated but remain weak and inconsistent [34–37]. As the etiology of CNS tumors remains poorly understood, more multicenter prospective studies in the future would help to achieve better consensus on the causal associations of brain tumor.

3 Clinical Presentation

Clinical presentation in a patient with CNS malignancy can be varied depending on the age, location of the tumor, size, and rate of growth. Tumors produce symptoms either by compression or infiltration of functioning nervous tissue. Mass effect due to increasing tumor bulk may lead to local (compressive symptoms) or symptoms due to raised intracranial pressure (ICP).

Neurologic deficit is seen in almost two-thirds of all brain tumors [38] and is usually progressive, though sudden acute neurological worsening may be associated with tumoral bleeds. Symptoms depend on the location of the tumor varying from subtle cognitive defects (like inability to perform routine tasks, emotional lability, forgetfulness, reduction in the range of mental activity, indifference to social practices, and behavioral changes) to more obvious "hard" neurological deficits like motor and speech defects. Figure 2 shows common symptoms associated with different locations of tumors.

Headache with/without vomiting can be the presenting symptom in 54% of the patients [39]. It may be associated with or without raised intracranial pressure (ICP), the latter being due to invasion or compression of pain-sensitive structures like dura, blood vessels, or periosteum.

Common symptoms suggesting raised ICP are headache, vomiting, diminution of vision, excessive somnolence, and new onset focal neurological deficits. Classic early morning headache described in the literature is seen infrequently.

Seizures may be seen in 26% of patients as a presenting symptom. Often, they are focal at onset (a function of cortical irritation due to the tumor) but may spread secondarily resulting in a generalized tonic-clonic convulsion (GTCS).

Tumors in sella/suprasellar location (pituitary adenoma, craniopharyngioma, etc.) would typically present with worsening visual field deficits due to compression of the optic chiasma. A secretory pituitary tumor would have manifestations of excessive hormone production like cushingoid features (cortisol excess), acromegaly (growth hormone excess), or very rarely hyperthyroidism. A large non-functioning sellar/suprasellar mass can also present with features of hypopituitarism due to compression of the pituitary gland.

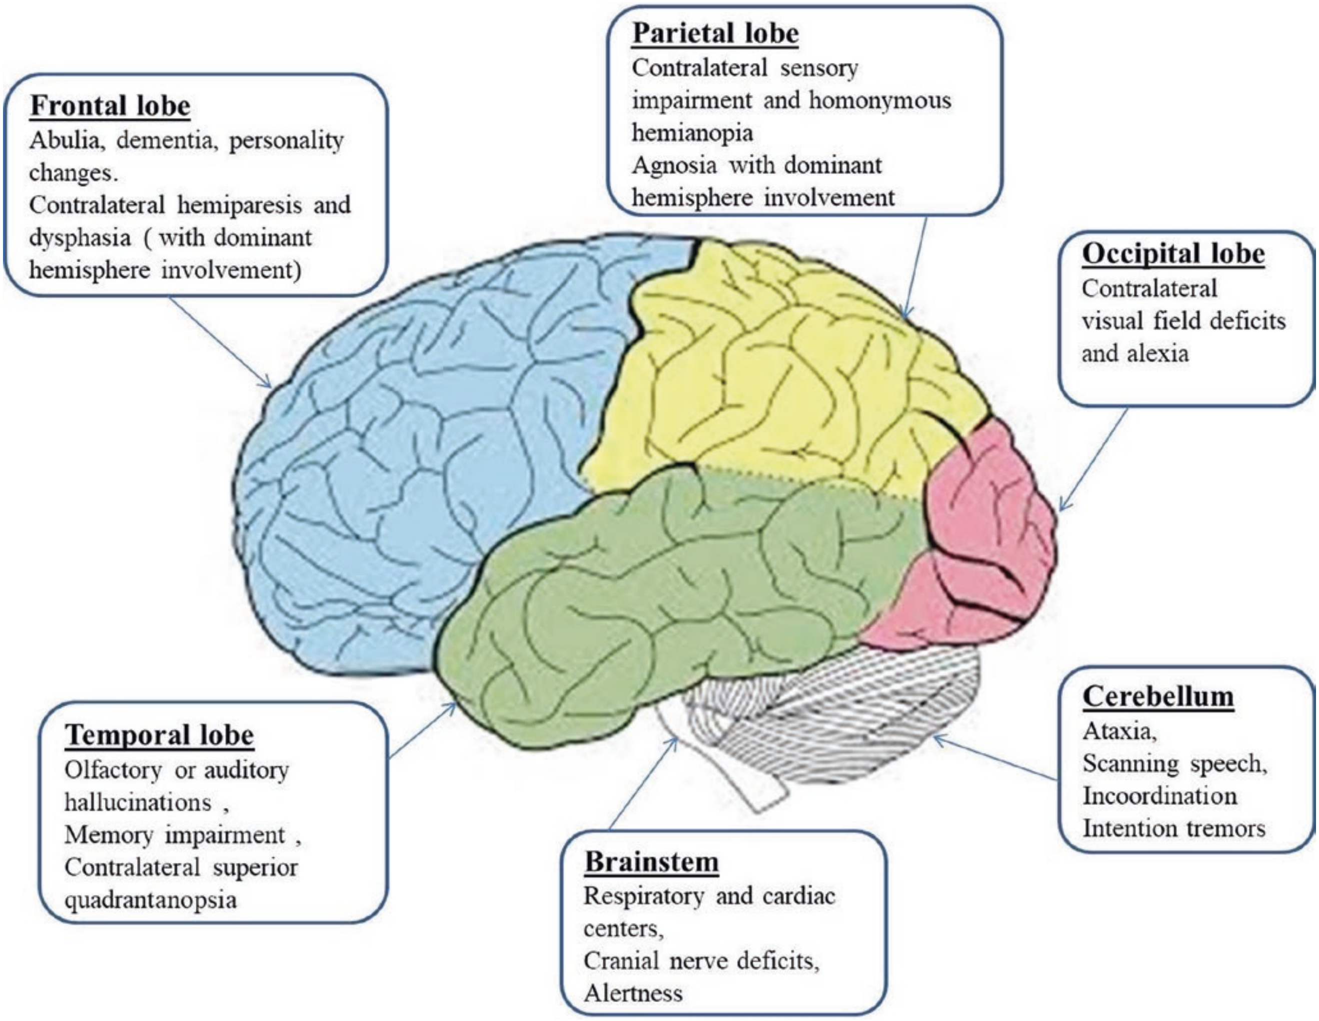
Tumors in the cerebello-pontine angle location have a characteristic sensori-neural type of hearing loss due to the involvement of vestibulo-cochlear nerve. There may be associated imbalance while walking, tinnitus, headaches, and facial nerve weakness with increasing tumor size due to local mass effect.

Intraventricular location, frontal and occipital poles are considered to be silent zones of the brain, and tumors at these locations do not manifest until they are very large, often only showing raised ICP features.

Signs and symptoms in spinal tumors depend upon the location (cervical, dorsal, lumbar, or sacral) or plane (extradural, intradural extra medullary, or intramedullary).

- Pain is the most common complaint. Radicular pain that increases with Valsalva and spine movement in a location uncommon for intervertebral disc disease should raise suspicion of a spinal cord tumor. Pain during recumbency ("nocturnal pain") is classic for spinal cord tumors.
- Motor disturbances. Quadriparesis (in cervical cord tumors) or paraperesis (in dorso-lumbar tumors) are frequent manifestations of intradural tumors.
- Syringomyelic syndrome. Syringomyelic syndrome suggests intra-medullary spinal cord tumors with syringomyelia. This includes lower motor neuron features (segmental weakness with loss of reflexes and muscle atrophy) in the upper limb and upper motor neuron features (increased tone, exaggerated reflexes) in the lower limbs.
- Dissociated sensory loss. Decreased pain and temperature with preserved light touch can be seen in intramedullary spinal cord tumors.
- Sphincter disturbances. Sphincter disturbances are sometimes seen and usually urogenital (anal less common) in nature, viz. hesitancy, retention, and incontinence. They may be early signs in conus/cauda equina lesions.

In all patients, a detailed neurological examination usually provides a clue to the diagnosis and is essential as a baseline examination during follow-up. Irrespective of the symptoms, a detailed neurological examination (and in brain tumors, a detailed neuropsychological evaluation) should be performed for all cases.



Frontal lobe
Abulia, dementia, personality changes.
Contralateral hemiparesis and dysphasia (with dominant hemisphere involvement)
Parietal lobe

4 Diagnostic Imaging and Work up

Several modalities may be used to aid in the diagnosis of primary and recurrent CNS tumors and assess the burden of the disease in cases with metastatic spread in the CNS. Computed tomography (CT) and magnetic resonance imaging (MRI) are the most commonly used imaging modalities. Although these modalities continue to evolve, advanced imaging techniques such as MR spectroscopy (MRS), diffusion-weighted MRI, CT and MR perfusion imaging, and bioimaging techniques like positron emission tomography (PET) are used routinely in clinical practice today for differentiating neoplastic disease from non-neoplastic ones. Functional MRI and diffusion tractography imaging (DTI) helps in intraoperative planning surgery in eloquent brain areas. These modalities also provide valuable information about the configuration of the lesion, vascularity, and tissue characteristics and relation to important surrounding neuro-vasculature Emerging research in texture analysis has spawned a new and exciting field of radiomics that has the potential to provide more detailed (including biological) information about tumors [40]. Thus, these investigations when used appropriately add significant information to the evaluation of patients with cerebral neoplasms.

CT brain with contrast is often the first screening tool for investigating a patient with suspected CNS neoplasm. Calcifications and bleed within the tumor can be particularly better assessed on a CT scan. CT angiography is sometimes used to assess the arterial supply and venous drainage of the tumors.

MRI is the gold standard for the evaluation of both brain and spine tumors. It provides reliable information on the probable histologic type and grade of the malignancy along with precise anatomical localization. A minimum mandatory

brain tumor MR protocol should include routine sequences as well as MR spectroscopy and MR perfusion. fMRI is particularly performed in patients with lesion adjacent to eloquent cortex to define its relation to tumor, especially when awake surgery has been planned. DTI helps to assess the proximity of the tumor to the deep white matter tracts. Both of these can be used intra-operatively to facilitate and tailor surgical resections (image-guided surgery).

4.1 Additional Investigations and Work-Up

In selected cases, additional workup may be required to aid diagnosis and stage tumors. Figure 3 shows a diagnostic evaluation plan for common CNS tumors.

CSF analysis for malignant cells is done to rule out leptomeningeal spread of the disease particularly in fourth ventricular and pineal mass lesions. CSF and serum estimation of tumor markers (alfa fetoprotein, LDH, beta-HCG) should be performed in suspected cases of germ cell tumors. In a patient with suspected sellar/suprasellar mass lesion (like pituitary adenoma, craniopharyngioma), ophthalmological evaluation (visual fields, visual acuity) and endocrinological evaluation (blood hormones) should be performed.

5 Pathology of CNS Tumors and Tissue Diagnosis

CNS tumors comprise a wide spectrum of pathologies, and tissue diagnosis is imperative for the institution of appropriate multimodal therapy. The 2021 WHO classification has led to a paradigm shift in the classification of CNS tumors emphasizing an integrated diagnosis comprising basic histo-morphology along with molecular characterization, the latter forming a crucial part of the overall diagnosis [41]. This has resulted in the reorganization of many histological entities and regrouping of tumor types and subtypes with distinct molecular signatures, reflecting biological behavior and having a direct impact on therapeutic strategies as outlined below. Tissue diagnosis, therefore, is a vital part of the overall management of CNS tumors. Unlike other solid tumors, diagnosis is usually achieved during surgical resection itself as a one-stage procedure (except in unresectable locations where only a surgical biopsy is performed, either open or stereotactically using mage guidance). The risk of surgical biopsy in critical locations is always weighed against the added benefit of tissue diagnosis over the radiological diagnosis. Rarely (as in diffuse pontine gliomas) is non-surgical therapy initiated without a tissue diagnosis, based only on radiological characterization.

6 Surgical Management

Surgery is usually the first modality of treatment in virtually all CNS tumors. In some benign tumors, it may be the only treatment required. The principles of surgery remain more or less the same for all tumor types (with differences in approaches and strategies depending on the location and occasionally the biological nature of the tumors).

Surgery serves the following roles:

1. Maximal safe resection (whenever possible) of the tumor without incurring fresh neurologic deficits is the primary goal of surgery. Due to the unique location of these tumors, it is often not possible to resect them radically (as in other oncological surgeries) and the underlying tenet always remains "safe maximal resection."
2. Tissue diagnosis (in unresectable tumors/suspected non-glial/non-neoplastic etiologies) can be achieved, so as to guide further adjuvant treatment.
3. Relieves compressive symptoms, which is a major indication of cytoreductive surgery and can often be life-saving.
4. Surgery also provides an opportunity to deliver novel local therapies (many of which are currently experimental).
5. Cytoreductive surgery also facilitates subsequent adjuvant therapies by reducing the tumor burden and eliminating the hypoxic (therapy-resistant) core tumor mass.

The general principles of neuro-oncological surgery are as follows:

1. Meticulous pre-surgical evaluation is mandatory and usually comprises of a thorough evaluation of pre-operative neurologic status, adequate imaging studies, counseling of the patient and family about the nature of the disease and possible need for adjuvant treatment, and taking informed consent.
2. The brain and spinal cord are eloquent areas, and this limits radical resection in neuro-oncological practice. Deciding the safest operative corridor for an individual patient is of paramount importance as the rigid bony skull often limits adequate exposure required for surgical excision maximizing the tumor resection with preservation of neurologic function is critical. Many adjuncts are used intraoperatively to achieve these goals.
3. Some patients seen in an emergency setting (intraventricular mass lesions) with obstructive hydrocephalus would warrant a CSF diversionary procedure like endoscopic third ventriculostomy or ventriculo-peritoneal shunt.
4. Post-operative care and rehabilitation. Post-operative imaging (MRI preferably) should be performed within 72 h of the surgery. Intensive monitoring in an ICU for the development of fresh neurologic deficits/neurologic worsening or metabolic abnormalities and providing prompt treatment is of utmost importance. Occasionally surgical procedures may result in significant morbidity. Intense rehabilitation measures instituted promptly help in the improvement of overall quality of life (QOL) and help consolidate further adjuvant treatment.

6.1 Adjuncts in Neuro-oncological Surgery

Many adjuncts have been used routinely in neurosurgical practice to achieve this goal of maximal safe resection, such as:

1. Microscope. It has been routinely used in neurosurgical procedures. It provides improved illumination, magnification, and stereoscopic view at depth thus facilitating more radical and complex surgeries safely.
2. Intra-operative navigation. Intra-operative navigation systems are based on pre-operative imaging and help to plan the incision, localize the tumor intra-operatively and assess completeness of the resection. However, due to technical limitations (brain shift), the role in guiding resections is usually limited.
3. Intraoperative imaging. This allows real-time updates and guides resection control overcoming the limitations of navigation. IOMR is the gold standard but remains a logistical challenge at most centers [42]. IOUS is a useful, cost-effective alternative [43]. Our own experience with navigating the US has been very encouraging [44, 45]. Optical imaging techniques like the use of fluorescence (5-aminolevulinic acid) administered before surgery help to guide and maximize tumor resections, especially in high-grade gliomas [46].
4. Intra-operative neuro-monitoring: It helps to identify eloquent areas (motor strip), cranial nerves, and white matter tracts (corticospinal tracts) intra-operatively and allows

prediction and prevention of neural injury. There has been a progressive increase in the published literature supporting the role of neuro-monitoring for maximal safe resection [47]. Awake mapping allows the mapping of many other language and cognitive functions permitting radical resections in eloquent regions.

5. Endoscopy. Endoscopic techniques have been frequently used as a minimally invasive tool for the resection of brain tumors, especially skull base tumors, pituitary adenomas, craniopharyngiomas, and intraventricular tumors.
6. Local surgical therapies. Various local surgical therapies have been developed, and many more are under development for treating malignant brain tumors. Some of these include Carmustine wafer (Gliadel wafers), nanotherm therapy, and laser interstitial thermal therapy (LITT), especially in recurrent glioblastomas.

7 Adjuvant Treatment for Brain Tumors

Adjuvant therapy is often used after surgery, to minimize the risk of recurrences and improve disease control. It includes radiation therapy (RT), chemotherapy, and targeted therapy usually given to target the residual tumor or microscopic disease post-surgery. Radiation therapy (RT) forms a very integral component in the multi-modal management of many CNS tumors. Over the last few years, modern techniques of radiotherapy like intensity-modulated radiation therapy (IMRT), image-guided radiation therapy (IGRT), volumetric-modulated arc therapy (VMAT), stereotactic radiotherapy (SRT), and particle therapy like proton beam therapy have been increasingly used to minimize the irradiation to the normal brain without compromising dose essential for tumor control [48].

7.1 Radiotherapy Techniques

Linear accelerators are being commonly used which has the advantages of higher energy photons as compared to telecobalt machines. The incorporation of beam modifications like multi-leaf collimators in linear accelerators can treat complex irregularly shaped tumors. These have helped in moving from two-dimensional to three-dimensional conformal radiotherapy (3DCRT) techniques by properly directing radiation beams from various directions. Further improvements had been possible by variation of beam intensities which is known as intensity-modulated radiotherapy (IMRT) or using image guidance (IGRT) to increase treatment accuracy.

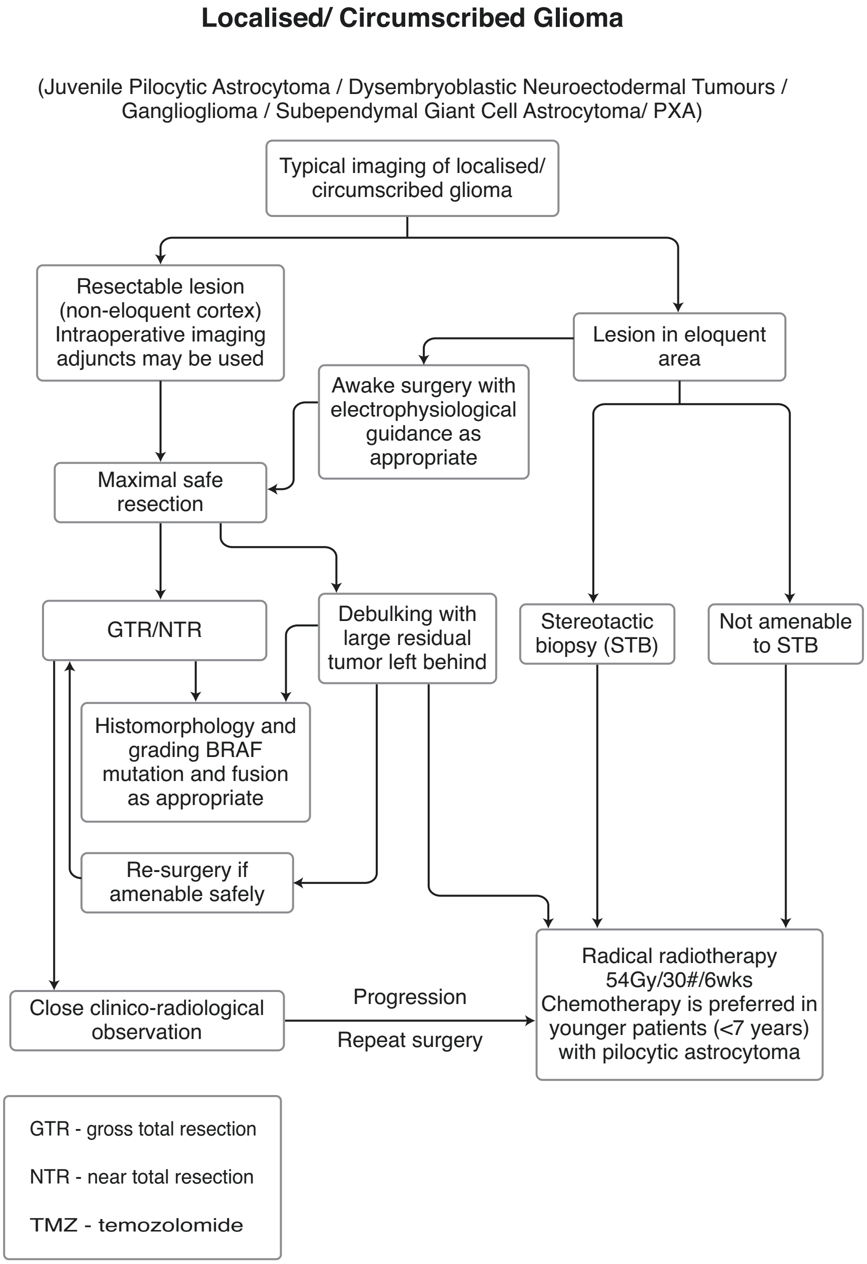
Proton beam radiation therapy (PT) allows dose reduction to normal tissues by allowing for more precise dose delivery due to the unique physical properties of protons known as a Bragg peak. This property permits tissue penetration to a variable depth, depending upon their energy, and deposit energy only at that depth in the tissue [49]. Protons have been shown to have unique and distinct advantages in terms of dose escalation, preservation of intelligence, and endocrine functions particularly in childhood and low-grade/benign tumors, reducing the incidence of second cancers because of lower integral dose and in cases of re-irradiation [50–52].

7.2 Systemic Therapy/Chemotherapy

Chemotherapy is used in neuro-oncology to augment the effect of radiotherapy, radio-sensitization, or for treatment of microscopic “out-of-field” tumor based on the principle of spatial cooperation. The intact blood–brain barrier (BBB) prevents access to the brain for several compounds and therefore achieving therapeutic concentrations remains an enormous challenge. Recent focus is on the generation of newer and effective systemic therapies, targeted agents, and immunotherapy agents for CNS tumors and many trials are currently ongoing [53]. Hereafter specific systemic therapies will be discussed with respect to the common tumor classes treated.

8 Management of Individual Tumor Types

This section will provide an overview of management principles for the commonly encountered tumor types. Whereas the WHO 2021 classification includes an exhaustive list of tumor types, treatment strategies for the more common tumors can be broadly grouped, and Figs. 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14 and 15 show the management pathways for these tumors followed at our center.



Localised/ Circumscribed Glioma

8.1 Circumscribed Gliomas and Glioneuronal/Neuronal Tumors

These are a group of tumors characterized by their low-grade (benign) potential and relatively circumscribed extent. The circumscribed gliomas comprise a diverse histological spectrum with pilocytic astrocytoma being the commonest variant (others being pilomyxoid astrocytoma, subependymal giant cell astrocytoma, pleomorphic xanthoastrocytoma [PXA]). Glioneuronal tumors are a separate histological group but clinically most behave and are treated like circumscribed gliomas. These tumors differ from diffuse gliomas by their well-defined delineation, earlier age of onset, lack of invasiveness, and favorable prognosis in many patients. Because of the circumscribed nature of these tumors, they may be amenable to complete resection and eventual cure.

Chemotherapy
High precision re-irradiation with TMZ in selected cases
Bevacizumab for recurrence/ progression in selected cases
Rechallenge with TMZ
Salvage PCV regimen

The primary treatment for circumscribed gliomas is usually maximal safe resection. However, eloquent location frequently precludes complete resection. Radiation is recommended for residual disease in proximity to critical structures (e.g., optico-chiasmatic gliomas) or recurrent/progressive disease that cannot be resected. Conformal techniques to deliver doses ranging from 50 to 54 Gy using dose fractions 1.8 to 2 Gy appear most appropriate. For radiation planning and delineation of tumor, appropriate MR sequences (mostly T2 FLAIR, T2 propeller) need consideration since these tumors are better visible in such sequences. Chemotherapy is often used in younger patients (usually <7 years) with Pilocytic astrocytomas in critical areas (opto-chiasmatic) to achieve tumor control or delay radiotherapy.

Our knowledge regarding the role of BRAF (gene mutation and fusion) in pediatric gliomas has evolved during the last few years. BRAF fusion has a favorable prognosis in pilocytic astrocytoma (70%) and while BRAF V600E mutation has favorable outcomes in PXA [54]. Novel BRAF inhibitors like Vemurafenib and Dabrafenib are under evaluation and may further optimize clinical outcomes in the future. The BRAF pathway is part of the larger complex RAS-RAF-MEK-ERK (MAP Kinase) pathway which is now recognized to be implicated in pediatric type low-grade gliomas, offering opportunities to be targeted using MEK inhibitors.

8.2 Adult Diffuse Gliomas

The term diffuse glioma encompasses the two common histologic subtypes of gliomas that occur in the cerebral hemispheres: diffuse astrocytoma and oligodendroglioma (ODG). The WHO 2021 classification has changed the classification

and definition of these common tumors. The earlier terminology of mixed glioma/oligoastrocytoma was done away with, being replaced by mandatory molecular characterization in the WHO 2021 classification. This group of tumors which is characterized by IDH (Isocitrate dehydrogenase) mutations are diffuse in nature with an infiltrative growth pattern which may preclude radical resection, especially at eloquent locations. They also have a protracted natural history, which in most instances culminates in transformation into high-grade gliomas. Treatment involves safe maximal resections (or biopsy if not resectable) for histological confirmation followed by adjuvant radiotherapy with or without additional chemotherapy depending upon the histologic and molecular subtypes.

Molecular markers have been incorporated in the new 2021 update of the WHO classification of CNS tumors. IDH mutation testing is a valuable diagnostic, prognostic, and predictive biomarker for the management of patients with glial tumors. IDH1 and IDH2 mutations occur (in a mutually exclusive manner) in nearly 80% of grades II and III oligodendroglioma and astrocytoma and are the defining molecular signature for this group of tumors and a strong prognostic biomarker in patients with glioma, being associated with a favorable outcome. The diagnosis of ODG requires a histological pattern of oligodendroglioma with the demonstration of both an IDH gene family mutation and combined whole-arm losses of 1p and 19q (1p/19q co-deletion). Diffusely infiltrating astrocytomas are genetically defined by the presence of IDH mutations in addition in nearly all cases TP53 mutations as well as, in a large fraction, α-thalassemia/mental retardation syndrome X linked (ATRX) mutations. IDH mutant astrocytic tumors showing histological features of grade 4 or homozygous deletions of CDKN2A/2B behave more aggressively. The WHO 2021 classification has identified pediatric type of diffuse gliomas as distinct from adult diffuse gliomas based on characteristic molecular signatures. These are IDH-wild type, with the high-grade pediatric type diffuse gliomas comprising of the histone altered tumors (see below) including the newly identified histone G34 tumors, and the lower grade ones made of predominantly MAPK pathway-altered tumors. Targeted therapy in pediatric gliomas is therefore an emerging and potentially useful alternative.

Patients with adult diffuse gliomas (WHO grade II astrocytoma or oligodendroglioma) having relatively high mitosis, high Mib-1 index, nuclear pleomorphism suggesting atypical histology for a low grade but not qualifying as grade III tumor on histopathology are known to behave more aggressively. Similarly, radiological features of even subtle but definite gadolinium enhancement and/or considerable

heterogeneity on T2 fluid-attenuated inversion recovery (FLAIR) sequences are also shown to be adverse prognostic marker. Patients with atypical histology may behave more like an anaplastic variant rather than pure low-grade glioma, and this group may be considered as aggressive low-grade glioma and treated with more intense protocols rather than observation or RT alone.

Surgery alone may not be curative (even if the lesion appears resectable) in patients with most diffuse intermediate-low grade glioma, and additional treatment may be required**.** Post-operative adjuvant treatment is generally required in the event of the presence of adverse factors such as, age ≥40 years, large preoperative tumor size (e.g., ≥5 cm), incomplete resection, astrocytic histology, elevated MIB-1 index (>3%), and absence of a 1p/19q-codeletion [55]. This management approach has been based on evidence gathered from two large cooperative group trials (RTOG 9402 and RTOG 0424 studies) [56–58]. Alkylating chemotherapy using the procarbazine, lomustine, and vincristine (PCV) regimen initially and temozolomide more recently plays an important role in the management of patients with low-grade gliomas. The RTOG 9802 trial compared radiotherapy alone with radiotherapy followed by six cycles of PCV chemotherapy [56].

Long-term results showed a survival benefit in the group which received radiotherapy and chemotherapy. PFS at 10 years was 51% in the group that received radiation therapy plus chemotherapy versus 21% in the group that received radiation therapy alone; the corresponding rates of overall survival at 10 years were 60% and 40%, respectively. Though widely used, evidence for the use of concurrent and adjuvant temozolomide is awaited from the results of the ongoing CODEL study (NCT00887146). In non-codeleted tumors, the CATNON study has demonstrated the benefit of adjuvant TMZ, though the benefit of concurrent TMZ remains to be seen [59].

Radiation dose is usually between 54 and 59.4 Gy in 30–33 fractions with concurrent TMZ followed by 12 monthly adjuvant TMZ cycles. Grade II aggressive low grade is treated to a dose of 54 Gy in 30 fractions. Grade III tumors require 59.4 Gy in 33 fractions with concurrent TMZ followed by 12 monthly TMZ cycles. However, there is emerging interest in giving 54–55.8 Gy in 31 fractions in co-deleted anaplastic oligodendroglioma.

8.3 Glioblastoma

Glioblastoma is the most common malignant primary brain tumor in adults. As per the 2021 WHO classification, glioblastoma is a diffuse astrocytoma with necrosis and microvascular proliferation and defined by the absence of IDH mutation. For lower-grade IDH wild-type astrocytic tumors, the presence of either EGFR mutation, chromosome 7 loss/10 gain, or TERT promoter mutation, is diagnostic of Glioblastoma. The standard of care for glioblastoma (GBM) is maximal safe surgical resection followed by adjuvant radiotherapy and chemotherapy (temozolomide). Even with the present multi-modality approach, the median survival is around 14–17 months with a high incidence of early recurrence. For the purpose of radiotherapy planning, the gross tumor volume commonly includes the T1-enhanced region with 2 cm clinical target volume and taking into account all relevant T2/Flair abnormality.

The dose and fractionation to be administered generally depend upon the patient's prognosis and performance status:

- Favorable prognosis patients: 59.4–60 Gy in 30 fractions over 6 weeks.
- Poor prognosis/performance patients: 35–40 Gy in 10 fractions over 2 weeks.

Hyper fractionated or hypo-fractionated regimens have not been shown to be associated with survival benefit [60]. Additionally stereotactic radiotherapy boost also has not been shown to prolong survival. In gliomatosis cerebri (a type of diffuse infiltrative high-grade glioma involving more than two lobes of the brain), whole brain radiotherapy to doses of 50 Gy or more achieves disease control in a proportion of carefully selected patients.

Temozolomide is an oral alkylating agent, recommended for concurrent chemo-radiotherapy and adjuvant chemotherapy in patients with glioblastoma [61]. Based on the pivotal phase III trial in which patients with glioblastoma were randomly assigned to postoperative radiation versus radiation plus concurrent temozolomide followed by up to six cycles of adjuvant temozolomide (150 mg/m^2 for first and 200 mg/m^2 for rest of the cycles). They observed that the addition of temozolomide increased the median survival to 15 months vs 12 months with radiotherapy alone.

Bevacizumab is a monoclonal antibody that binds to the vascular endothelial growth factor (VEGF), which plays a critical role in the development of the abnormal vasculature observed in high-grade gliomas and other tumors. Phase II studies using bevacizumab conducted in previously treated patients with high-grade glioma demonstrated a reduction in steroid requirement and imaging evidence of tumor response. These results led to the approval of bevacizumab for recurrent high-grade glioma. The AVAGlio and RTOG 0825 trials exploring bevacizumab versus placebo in the newly diagnosed setting prolonged PFS but not OS, and therefore, it is not a standard of care in the upfront setting.

At recurrence, there is no accepted standard of care and treatment recommendations vary. Management options include repeat surgery or re-irradiation in case of recurrent disease. Second-line systemic therapies, such as anti-angiogenic drugs (bevacizumab), alkylating agents (CCNU), and platinum or newer experimental treatment options like loco-regional injection of replicating viruses, novel chemotherapy agents, epidermal growth factor receptor (EGFR) targeting compounds, or immunotherapy protocols, can be used as per patient requirement.

Combined modality therapy is the standard of care for younger patients with glioblastoma. Toxicity and side effects become more closely balanced with benefits in elderly patients where more convenient shorter courses of radiotherapy (40 Gy in 15 fractions) are commonly used. Recently, the addition of temozolomide (concurrent and adjuvant) to short-course radiotherapy resulted in longer survival than short-course radiotherapy alone, as per a large multi-intuitional randomized controlled trial [62].

Alternating electric fields: A portable medical device applied to the scalp that generates low-intensity alternating electric fields first became available in 2011 for the treatment of recurrent glioblastoma. Experimentally, the biologic activity of the therapy is reported to derive from an anti-mitotic effect imposed by the alternating electric fields, which exert forces on charged tubulin subunits and thereby interfere with the formation of the mitotic spindle. The results of a subsequent open-label randomized trial suggest that the device may improve both progression-free and overall survival when used along with monthly temozolomide in patients with newly diagnosed glioblastoma in the post-radiation setting [63].

Investigational therapies: A variety of therapies are being explored in clinical trials for patients with newly diagnosed glioblastoma. Ongoing studies looking into sub-ventricular zone (SVZ) irradiation and its outcomes have resulted in mixed outcomes and need a carefully done prospective study to evaluate its firm role conclusively [64]. Most studies are testing either molecularly targeted agents or biologic approaches such as immunotherapy, vaccine-based therapies, or local gene therapy. The high expression of checkpoint molecules, in particular, the programmed death ligand-1 (PD-L1) in GBM suggests that PD-L1 can be a good target for further clinical research [65]. H3.3 G34-mutant gliomas is a newly defined high grade (Grade 4) type of glioma classified as pediatric type high-grade glioma (earlier included as glioblastoma), which has a slightly better prognosis than IDH wt glioblastoma and may be amenable to targeted therapy.

8.4 Brainstem and Midline Gliomas

The term brainstem glioma refers to both focal (20%) and diffuse intrinsic (80%) tumors. Patients with diffuse intrinsic tumors typically have a worse prognosis, with a median overall survival of not more than 12 months. Diffuse midline glioma (H3 K27M–altered) is a new entity classified as pediatric type high-grade glioma as per the 2021WHO classification of CNS tumors. The H3 K27M–altered (H3F3A/-HIST1H3B/C) diffuse midline gliomas usually appear histologically as astrocytic tumors. There are clinical situations where there is a clinico-radiological dilemma in midline gliomas (e.g., thalamic) between a low-grade pilocytic and high-grade tumor. Histone mutation status can help achieve correct diagnosis and appropriate management [41].

Given the location of these tumors, surgical resection is usually not possible. Radiation therapy is the only treatment that appears to alter the clinical course of diffuse intrinsic pontine gliomas. Despite multiple trials of dose-escalation, altered fractionation, and radio-sensitization, none of these modulations has been proven more effective than conventionally delivered radiation therapy. Although the degree of tumor shrinkage induced by radiation therapy can be dramatic, the response is generally transient and patients are not cured by this approach. Concurrent chemotherapy has not demonstrated a benefit, nor have other strategies. The identification of novel molecular pathways in diffuse intrinsic pontine gliomas offers the opportunity for their inhibition. The identification of the phospoinositide 3 kinase (PI3K) and sonic hedgehog pathway as possible activating events in xenograft tumors are now being explored as potential targets with molecular therapies [66].

8.5 Ependymal Tumors

Ependymomas are a group of glial tumors that typically arise within or adjacent to the ependymal lining of the ventricular system and account for less than 10% of tumors arising in the CNS. They form a wide spectrum of tumors differing in histology, location, and age groups. They are usually well demarcated with frequent areas of calcification, hemorrhage, and cysts. With improvements in the molecular classification of tumors, genomic data are now being incorporated into the characterization and prognostication of these tumors, for example, RELA fusion-positive (now called ZFTA positive) ependymoma, which predominates in the supratentorial region, have a poor prognosis, are now part of the WHO 2021 update [41]. Surgical resection is usually the first treatment, and the extent of resection is a very important prognostic factor. Radiation is usually considered for grade II ependymal tumors with residual disease post-surgery, grade III histology, and for recurrent tumors. There has been a concern of neurocognitive decline in younger patients (age <3 year), and radiation can be delayed with the use of chemotherapy, especially for supratentorial ependymomas. For grade II ependymoma, 50–55 Gy is delivered using conventional fractionation with a conformal technique. For grade III, higher doses are needed in the range of 55–60 Gy. Few high-grade ependymomas presenting with disseminated metastases may need CSI or an extended field of treatment.

Chemotherapy may have a role in delaying or avoiding postoperative cranial irradiation in children less than 3 years old. There are no randomized trials comparing immediate RT following surgery with a strategy in which surgery is followed by chemotherapy, and RT is deferred. Cisplatin, carboplatin, and etoposide appear to be the most active agents, and higher response rates have been observed with more intense combination regimens. The benefit of adjuvant chemotherapy after surgery and postoperative RT is unclear and needs further evaluation.

8.6 Embryonal Tumors

Embryonal tumors typically occur in infants and young children. The most common tumor in this group are medulloblastomas; other tumor types include embryonal tumor with multi-layered rosettes (ETMR), atypical teratoid/rhabdoid tumors (ATRT), and many new molecularly defined CNS embryonal tumor types, previously called CNS primitive neuro-ectodermal tumor (PNET).

Molecular classification using expression profiling or whole-genome methylation analysis has classified medulloblastoma (MB) into four groups: WNT-activated, SHH-activated, group 3 and group 4 MB with specific demographic, clinico-radiological and prognostic features [67, 68]. Table 1 shows the risk stratification based on these subgroups. A certain overlap between histopathological variants and molecular groups was demonstrated: WNT-activated MBs usually have a classical phenotype, SHH-activated TP53-wild-type tumors often show a desmoplastic/extensive nodularity phenotype, and SHH-activated TP53-mutant tumors and group 3 MB frequently present as large cell/anaplastic

Table 1 Molecular risk stratification in medulloblastomas

Risk groups	Molecular sub-group (histopathologic variant)
Low	WNT-activated MB (classic phenotype) Group 4 MB with chromosome 11 loss or 17 gain
Standard	SHH-activated MB without TP53 mutations/without MYC amplification (desmoplastic/extensive nodularity) Group 3 (large cell/anaplastic) and group 4 (with intact chromosome 11) MB
High/very high	SHH-activated MB with TP53 mutations (large cell/anaplastic) or MYC amplification All groups (except WNT) with metastases

appearance. A number of clinical trials are ongoing to optimize therapies with a view to de-escalate (e.g. lower the RT dose and volume in very favorable WNT pathways) or escalate the therapies in high and very high-risk groups.

Radiation planning and delivery need special care considering the technical challenges associated with cranio-spinal irradiation (CSI) since these tumors are associated with high rates of leptomeningeal seeding. For pediatric patients less than 3 years, radiation is avoided upfront with the use of chemotherapy. For average-risk patients, radiation consists of a reduced dose CSI to a dose of 24–30 Gy using 1.6–1.8 Gy per fraction. Post CSI, the tumor bed in the posterior fossa needs further radiation with a CTV margin of 10–20 mm to receive a total dose of 54–56 Gy. For high risk, a higher dose of CSI is delivered ranging from 30 to 36 Gy followed by boost to tumor bed or entire posterior fossa till 54 to 60 Gy. Metastatic deposits in the brain and spine are also boosted individually after CSI, although the total dose delivered to the spinal disease is limited by its higher radio-sensitivity. The challenge with CSI remains the length of the treatment field which needs to be covered with multiple radiation beams in a linear accelerator increasing dosimetry uncertainties. Quality control is essential with CSI, cautioned by failures reported over field edges (cribriform plates, spinal canal). Similar strategies are followed for other embryonal tumors like PNET, atypical teratoid/rhabdoid tumor (ATRT) with the use of CSI followed by a boost to local sites of disease.

In the standard risk group, reduced doses cranio-spinal irradiation is usually combined with weekly concurrent vincristine and followed by a multidrug regimen that can be cisplatin, vincristine and lomustine, or cisplatin, vincristine, and cyclophosphamide (Packer regimen). Five-year event-free survival (EFS) based on this regimen is over 80%. For high-risk groups, CSI is combined with weekly concurrent carboplatin followed by 6 cycles of a multi-drug regimen consisting of cisplatin, vincristine, and cyclophosphamide.

8.7 Meningioma

Meningiomas account for one-third of the primary CNS tumors in adults with Grade I meningioma accounting for 90%, atypical meningioma 5–7%, and malignant meningioma 1–3% [69]. Surgery remains the mainstay of these tumors with recurrence rates directly related to the extent of resection [70]. However, meningiomas in certain locations (especially skull base) may not be completely resectable. Atypical meningiomas are also associated with high recurrences, and while adjuvant RT is frequently considered for these tumors, optimal timing of its administration is not well established with ongoing studies attempting to define its exact role. Anaplastic meningiomas arise either de novo or may be associated with prior radiation and usually have poor prognosis with recurrence rates 50–94% and overall survival of only 2–5 years. TERT promoter mutation has been shown to have a prognostic relationship with these tumors, with a median time to progression among mutant cases being 10.1 months compared with 179.0 months among wild-type cases [71].

Compared to conventional radiotherapy and three-dimensional conformal radiotherapy, IMRT is useful in tumors close to critical areas, especially the skull base. IMRT delivered by segmental, dynamic, and arc-based IMRT techniques produces equivalent target coverage and avoidance of critical structures, improves local control, and reduces toxicity. Typical RT doses are as follows:

- Grade I: 54 Gy in 30 fractions
- Grade II (atypical meningioma): 55.8–60 Gy in 30–31 fractions
- Grade III (anaplastic meningioma): 60 Gy in 30 fractions

Stereotactic radiosurgery (SRS) may also be considered for recurrent, small, grade I lesions located in close proximity to critical structures with a dose delivered to be between 10 and 14 Gy. Grade II and grade III lesions are generally not suitable for SRS, as the target volume will not encompass the subclinical disease. Most chemotherapeutic agents have minimal or no activity against meningiomas. Agents such as hydroxyurea, dacarbazine, ifosphomide, temozolomide, irinotecan, and alpha-interferons have been studied with negative results. Emerging data suggest that drugs designed to target pathways such as EGFR, mTOR, PDGF, and VEGF involved in cell growth, proliferation, and angiogenesis may prove valuable in therapy.

8.8 Pituitary Adenoma

Optimal management of pituitary adenomas involves surgery, medical therapy, and radiation therapy. Trans-spenoidal resection (endoscopic or microscopic) remains the gold standard for most pituitary adenomas. The goal of surgery is to remove the tumor, relieve compression of the optic apparatus, and achieve biochemical cure (in secretory tumors). The WHO 2021 classification has introduced the new term Pituitary neuroendocrine tumor (PitNET) for these tumors and recommends classifying these tumors by their adenohypophyseal cell lineage using combined immunohistochemical expression of pituitary hormones and transcription factors. Radiation therapy is considered for clinically non-functioning adenomas in the following:

- Residual tumor after surgery. Continued growth is approximately 30–60% at 5 years when adenoma tissue, detected by MRI, remains after surgery [72]. Alternatively, the residual tumor can also be monitored if the patient is not symptomatic and the potential long-term side effects of radiation therapy can be avoided or at least postponed. Residual tumor in cavernous sinus especially mandates consideration for radiation therapy.
- Recurrent tumors: Surgical resection of recurrent tumor is advisable if possible. Even after complete re-excision, the chances of recurrence are about 5% at 5 years and up to 10–25% at 10 years [73]. RT is indicated in these cases (also directly when surgery is not possible/subtotal).

Management of patients with functioning adenomas (acromegaly, Cushings) includes surgical removal of the tumor, RT, and medical management [somatostatin analogs/dopamine agonists]. Surgery remains the initial treatment of choice in these patients with remission rates of 85% for micro-adenomas and 40–50% for macro-adenomas. A good proportion of these patients may require RT/medical management at some point of time in their course to achieve durable local and biochemical tumor control. Radiotherapy may not achieve immediate biochemical control, and often medical management (hormonal) is required to bridge the interim period.

Modern conformal fractionated radiation therapy (IMRT, SCRT, and protons) is generally the preferred mode of therapy for pituitary adenoma with a dose of 45 Gy in 25 fractions at 1.8 Gy daily fractions. In functioning adenomas, the radiotherapy target volume should be the entire sella, which is likely to harbor microscopic extension and such strategies have been shown to be very effective for anatomical and biochemical long-term tumor control [74].

8.9 Acoustic Neuroma

Acoustic neuromas account for approximately 8% of intracranial tumors in adults and 80–90% of tumors of the cerebello-pontine angle. The median age at diagnosis is approximately 50 years. They also occur with NF-2 and may often be bilateral. Various treatment options for acoustic neuroma include observation, surgery alone, and radiation therapy. Older patients with small tumors and limited hearing loss are usually observed with serial imaging and audiometry. However, these patients should be monitored annually for evidence of tumor progression. Surgery generally results in satisfactory long-term control of vestibular schwannomas though a 10-year recurrence rate for partially resected schwannomas can be 20% [75].

Radiation therapy approaches include conventional fractionated radiation therapy, stereotactic radio surgery (SRS), stereotactic radiotherapy, and proton beam therapy. There are no randomized trials comparing different radiation therapy approaches, and data are available from observational studies. Radio surgery (SRS) is a viable treatment option for selected patients with smaller tumors (<3 cm) with PFS at 5 years 90–95%. SRS may be associated with a risk of damage to VII and VIII nerves. It is a treatment option for small tumors who have lost serviceable hearing. Alternately, fractionated stereotactic radiotherapy (SRT) is potentially a better option in which similar tumor control can be achieved with decreased neurotoxicity [76]. Early experience using proton therapy for vestibular schwannoma treatment looks encouraging with 2- and 5-year local control rates of 95% and 94%, respectively. However, long-term follow-up data will be required for usage in routine clinical practice.

8.10 Craniopharyngioma

Craniopharyngiomas are the most common tumors arising from the pituitary region apart from pituitary adenomas. They are commoner in children than adults. These tumors are partly solid and cystic and can have dense areas of calcification. Craniopharyngiomas spark intense reactions from the adjacent brain due to their papillary projections, especially around hypothalamus. This often limits attempts at radical resection (both open and endoscopic). Published literature has revealed good local control in patients where conservative surgery followed by conformal RT protocols is performed for incompletely resected and/or recurrent craniopharyngiomas. This technique also avoids complications of radical surgery. A phase-2 study of conformal RT in midline craniopharyngiomas and low-grade gliomas demonstrated the advantage of using high-precision conformal RT in stabilizing verbal learning and visual auditory learning domains. Completely excised tumors can be observed (local control 85–100% at 5 years). For residual tumors, post-operative conformal RT (SRT/IMRT/Proton beam) to 54 Gy at 1.8-Gy per fraction is preferred (local control 85–100% at 5 years).

8.11 Primary Central Nervous System Lymphoma (PCNSL)

PCNLs are commonly associated with severe immunodeficiency (typically AIDS) and have an inferior prognosis. In the immunocompetent population, PCNSLs typically appear in older patients (median—60 years). High-dose methotrexate therapy in patients with PCNSL is intense, requires close observation, and is considered in patients with good performance status. Standard chemotherapeutic regimens for systemic lymphoma such as CHOP are ineffective in PCNSL, due to poor BBB penetration. Treatment with irradiation and corticosteroids often only produces a partial response, and recurrence is inevitable in more than 90% of patients. It may be considered in palliative setting in patients with poor performance score. Radiation is not recommended in conjunction with methotrexate because of an increased risk of leukoencephalopathy and dementia in patients older than 60 years.

8.12 Germ Cell Tumor

Germ cell tumors (GCTs) constitute 0.4% of all CNS tumors with the incidence of 3.7% in children. They usually occur in the pineal region (as well as sellar-suprasellar and other intraventricular sites). Surgical intervention usually consists of a biopsy to confirm the histopathological diagnosis (in a small subset with negative/equivocal tumor markers) and CSF diversion procedures to relieve the ICP. Non-germinomatous GCTs usually have elevated tumor markers (serum/CSF or both), which obviates the need for histologic diagnosis and the patient can be planned for definitive treatment. CSF cutoff values for NGGCT vary among different treatment groups (Table 2). The prognosis (Table 3) and treatment vary between the different types of GCTs.

Germinoma:

- Four cycles of chemotherapy followed by 40 Gy whole ventricular RT, if CSF-negative and no metastases.
- If CSF-positive or metastatic disease, 4 cycles followed by 24 Gy CSI at 1.5 Gy per fraction and 16 Gy boost to the tumor bed and bulky metastatic sites.

Non-germinomatous germ cell tumor:

- Four cycles of chemotherapy followed by 30–35 Gy CSI at 1.5 per fraction and 20 Gy boost to tumor bed and bulky metastatic sites.
- Surgery if residual disease at the end of therapy.

Table 2 Tumor markers for non-germinomatous germ cell tumors

NGGCT	The United States and Europe Groups	Asian and a few European Groups
CSF and serum AFP	>10 ng/dL	>50 ng/dL
CSF and serum beta HCG	>50 mIU/mL	>100 mIU/mL

Table 3 Prognostication among GCT

Prognostication	
Good	Pure germinoma Mature teratoma
Intermediate	Germinoma with elevated beta-HCG Immature teratoma Teratoma with malignant transformation
Poor	Choriocarcinoma Yolk sac tumor Embryonal carcinoma

8.13 Brain Metastases

Metastases are the most common intracranial tumors in adults (10–30%). Metastases from the lung, breast, melanoma, kidney, and colon are the most common intracranial malignancies. Historically, the overall survival after diagnosis of brain metastasis was poor. However, improvements in systemic disease therapies and multimodality brain metastasis treatment have improved the outcomes in brain metastasis patients. Following factors help in determining the management plan and eventual outcome—status of the primary disease, the extent of systemic burden of the disease, multiplicity of lesions in the brain and resectability, disease-free interval, and molecular targets (if applicable). The primary approaches to the treatment of brain metastases include surgery, stereotactic radiosurgery (SRS), and whole-brain radiation therapy (WBRT). WBRT remains the primary treatment modality for patients with a high intracranial tumor burden. The routine role of WBRT as adjunctive therapy in patients who are candidates for SRS/SRT or surgical resection has evolved. Randomized trials have shown in selected candidates where SRS/SRT is indicated, patients have a better quality of life, especially with regard to neuro-cognition.

9 Patient Reported Outcomes/Quality of Life (QOL)

Quality of life is a multidimensional concept used to measure patients' functioning and well-being. In recent decades, it has become an important outcome measure in clinical trials for brain tumor patients. However, QOL cannot be used alone to outcome measure for assessing the level of functioning and well-being of the patients and alternative tools, such as MD Anderson Symptom Inventory (MDASI) provide a more complete picture of functioning in daily life. Several patient-related, treatment-related, and sociocultural factors influence QOL scores. Various factors influence QOL scores in high-grade gliomas (HGGs) and low-grade gliomas (LGGs) in which the tumor itself appears to be one of the major factors influencing cognitive function and QOL domain scores. Patients with controlled disease have the most preserved QOL domain scores, whereas there are impairments in progression. Other tumor-related factors influencing QOL scores are tumor site, laterality, size, hypothalamic involvement, hormonal deficiencies, and epilepsy. Anticonvulsants, corticosteroids, new neurological deficits, higher dose of radiation therapy, and chemotherapy all have detrimental effects on QOL scores. Complete surgical resection, radiation therapy in HGGs, or low dose per fraction radiation therapy in LGGs with loco-regional control will improve or maintain QOL. The Response Assessment in Neuro-Oncology-Patient-Reported Outcome (RANO-PRO) working group recently highlighted the application of appropriate PRO instruments, with respect to its content and measurement properties (i.e., research question, content validity, and other measurement properties), in brain tumor research to generate high-quality evidence [77]. QOL is increasingly being adopted to determine the cost-effectiveness of various new modalities of treatment in cancer care (e.g., proton beam therapy).

9.1 Survivorship

With improving therapies, patients tend to survive longer. This often exposes them ironically to the consequences of the same therapies (usually radiotherapy) that have prolonged the survival. These toxicities may appear from months to years after radiation is delivered and a majority of them tend to be irreversible. Radio-necrosis is a dose-dependent effect usually affecting mostly during 6 and 24 months in 5–10% of patients in the high-dose region. Other major late sequelae with cranial radiation are neurocognitive decline, endocrinal dysfunction, hearing abnormalities, increased risk of cerebrovascular disease, radiation-induced second malignancies with significant implications on quality of life [78]. Neurocognitive affection in patients with brain tumors is multifactorial contributed by the disease itself, further worsening happening from surgical intervention and adjuvant treatment with radiation and/or chemotherapy. Hypopituitarism may affect 30–90% of patients (all age groups) receiving cranial radiation with deficiencies depending on doses to hypothalamic–pituitary axis [79]. Similarly, sensorineural hearing loss (10–20%, more frequent with doses >35 Gy to cochlea, platinum chemotherapy having an additive role) and increased risk of cerebrovascular events (8–16 times increased risk, higher chances with >40 Gy to circle of Willis) can be reduced by limiting doses to respective organs [80]. Long-term follow-up on a regular basis may help in early identification and treatment like hormonal support for endocrinal deficiencies or psycho-social support.

9.2 Mitigating Adverse Events

Radiation treatment for brain tumors continues to undergo rapid technologic advances with the implementation of highly precise conformal RT techniques such as IMRT, SRS, SRT, and protons, which may minimize the volume of normal tissue receiving high radiation doses. Jalali et al. in a large phase III randomized trial with carefully chosen and clinically relevant endpoints demonstrated that with modern technology tight radiation margins around the tumor can be achieved without compromising on local control and overall survival [81]. Further refinements in proton beam therapy technology using pencil beam scanning and image guidance are likely to further improve the efficacy of radiation therapy. The radiation dose delivered to frontal and temporal lobes has recently emerged as a predictive factor for the late neurocognitive decline. The hippocampus is particularly vulnerable to radiation dose-dependent neurocognitive decline, and whenever possible, hippocampal-sparing radiation is to be delivered [82].

With advances in diagnosis and treatment of brain tumors, survival is growing in number as well as duration. Currently, a lot of emphasis and focus is on advocacy and survivorship issues faced by brain tumor patients. Various international organizations are involved in a wide range of advocacy activities from raising public awareness of the challenges of brain tumors to advocating for equal access to promising new therapies to encouraging the establishment of brain tumor patient and caregiver support groups in countries where they do not exist. They help in collaboration with different government agencies, health professional and cancer organizations, clinicians and research institutes, and patient advocacy organizations around the world. The importance of the role of caregivers has been highlighted as they play a very important role in supporting a person diagnosed with a brain tumor, providing physical, emotional, and practical care depending on the treatment period which may last for a few months or longer.

In conclusion, contemporary neuro-oncology practice with evolving information based on pathology, radiological features, molecular advances, and the complexities of treatment involved, mandates discussion of every case in a multidisciplinary team approach (tumor boards) such that treatment plans incorporating all treatment modalities including modern adjuvant therapies, are optimized for maximum efficacy suiting the needs of the patients.

Acknowledgments The authors acknowledge input and contributions from colleagues from the Neuro Oncology Disease Management Group, especially Dr. Prakash Shetty, Dr. Tejpal Gupta, Dr. Girish Chinnaswamy, Dr. Jayant Goda, Dr. Epari Sridhar, and Ms. Nazia Bano.

EGFR	Epidermal growth factor receptor
FNAC	Fine needle aspiration cytology
HNC	Head and neck cancers
SCC	Squamous cell carcinomas

1 Introduction

Head and neck cancer is synonymous with squamous cell carcinomas (SCC) arising in the mucosa of the head and neck region and is historically associated with the heavy and prolonged use of tobacco. It is a major public health problem worldwide and is responsible for 4.8% of cancer-related deaths globally [1]. Head and neck cancer is comprised of various subsites, which are diverse in their etiology, epidemiology, presentation, and treatment. Though heterogeneous, these subsites are typically discussed together due to similarities in their management. This chapter provides a brief overview of incidence, etiology, and clinical presentation and outlines general principles of management of squamous cell carcinoma of the oral cavity, oropharynx, larynx, hypopharynx, nasopharynx, and paranasal sinuses.

2 Incidence and Epidemiology in India and Global

Head and neck cancers (HNC) account for 4.9% of all cancers globally and 19.5% of all cancer incidences in India [1]. It is the second-most common cancer in India with a male-to-female ratio of 3.6:1 and is responsible for 17% of cancer-related deaths in India [1]. It is typically associated with tobacco and alcohol consumption and the observed differences in the incidence of HNC between India and western countries are due to differences in cultural habits (oral tobacco and betel/areca nut usage) [2–5].

The decline in the smoking-related oral cavity and laryngeal cancers in the United States saw a simultaneous increase in oropharyngeal cancers, attributable to increased rates of infection with high-risk human papillomavirus (most commonly subtype 16) [6–8] secondary to an increase in high-risk sexual behaviors. The prevalence of HPV in oropharyngeal SCC ranges between 28% and 68% in the western literature [9, 10], while the Indian data show a lower prevalence (20–22.8%) [11, 12].

Inherited predisposition to SCC of the head and neck may be seen in conditions like Fanconi anemia, Li-Fraumeni syndrome, xeroderma pigmentosum, and ataxia telangiectasia.

The incidence of nasopharyngeal carcinoma is low in most parts of India (<1 per 10,000) and commonly seen in the North-Eastern part of the country with Nagaland state having the highest incidence (21/100,000) for males and Aizawl registry having the highest AARs (5.2/100,000) for females [13, 14].

3 Clinical Presentation in India and Worldwide

Tobacco-related cancers of the oral cavity, larynx, and hypopharynx are typically present in the fifth or sixth decade. In India with oral tobacco usage, the patients present almost a decade earlier [15].

Table 1 Common presenting symptoms in head and neck cancers

Oral cavity cancer	Oropharynx	Larynx and hypopharynx	Nasal cavity and PNS	Nasopharyngeal cancer
Nonhealing ulcer	Growth/mass	Hoarseness	Nasal obstruction	Painless neck swelling
Exophytic mass	Odynophagia	Change in voice	Epistaxis	Epistaxis
White/red patch	Otalgia	Dysphagia	Proptosis	Nasal obstruction
Per-oral growth	Dysphagia	Weight loss	Per-oral growth	Aural symptoms
Ankyloglossia	Trismus	Stridor	Trismus	Headache
Local pain/ referred to an ear	Large neck nodes—necrotic/conglomerate	Local pain/referred to an ear	Neurological symptoms; headache and cranial nerve deficits	Neurological symptoms; headache, diplopia
Neck swelling		Neck swelling	Neck swelling	Trismus
		Systemic symptoms; due to distant metastases		Systemic symptoms due to distant metastases; bone pain, cough, etc.

HPV-related HNSCC is also seen earlier than tobacco-related cancers. A typical patient with HPV-positive SCCHN is a young male with a median age varying from 54 to 57 years [16–18]. Common presenting symptoms in head and neck cancers are highlighted in Table 1.

An asymptomatic neck mass at presentation without obvious oropharyngeal lesions ('unknown primary') is common in HPV-positive disease, while local symptoms are typical in HPV-negative disease. While distant metastases are uncommon at presentation in most HNCs, higher rates of metastases may be seen in nasopharyngeal, HPV-positive oropharyngeal, and hypopharyngeal cancers.

4 Evaluation and Work-Up

4.1 History

- Disease-related information
- History of habits and addictions
- Medical and family history, including any prior malignancy
- Comorbidity

4.2 Physical Examination

- Performance and nutrition status assessment
- Documentation of the extent of the primary tumor and the neck node (size, number, level)
- Clinical evaluation for inoperability: fixity to underlying structures, extensive dermal edema, skull base, and carotid involvement
- Cranial nerve examination especially in cases of nasopharyngeal and paranasal sinus tumors
- Histological diagnosis—fine needle aspiration cytology (FNAC)/biopsy/slide review

4.3 Endoscopy and Biopsy

- Endoscopy (rigid/flexible) to map the extent of the primary disease and rule out synchronous primary, especially in hypopharyngeal cancers
- Evaluation under anesthesia if the endoscopic evaluation is inadequate
- Biopsy of the lesion for histological confirmation, histological subtype, and grade
- FNAC from the nodes
- Assessment of HPV status in oropharyngeal cancers using the p16 expression
- EBERISH in tissue or measurement of EBV titers for nasopharyngeal cancers
- HPV and EBERISH in metastases of unknown primary

4.4 Radiology

Imaging is essential for most intermediate and advanced cancers for assessment of locoregional extent. Radiological evaluation provides an anatomic tumor map for treatment planning, and prognostication, especially in residual/recurrent disease. CT, MRI, and FDG PET CT have widely used imaging modalities in the current practice for the diagnosis, staging, treatment planning, response evaluation, and follow-up of head and neck cancers.

A contrast-enhanced **CT scan giving a better delineation of cartilage and bone erosion** makes it the imaging of choice for gingivobuccal, laryngeal, and hypopharyngeal cancers. The extent of mandibular erosion is important for planning resection as well as a prognostic criterion. CT also has a complementary role in evaluating paranasal sinuses and skull bases. CT, however, is of limited use in the assessment of perineural spread, dural involvement, and marrow infiltration.

MRI is the preferred modality for imaging the suprahyoid neck which includes the nasopharynx, oropharynx, anterior tongue and hard palate, salivary glands, and paranasal sinuses, owing to its superiority over CT [19] in assessing, primary tumor invasion into surrounding soft tissue and bony structures [20], skull base invasion, intracranial extension, cavernous sinus extension, perineural spread [21], paravertebral space invasion and distinguishing the primary tumor from retropharyngeal lymphadenopathy.

In assessing **cervical nodal metastasis**, CT and MRI have similar sensitivity and specificity, Ultrasound-guided FNAC having the highest sensitivity/specificity for the evaluation of cervical lymphadenopathy [22].

FDG PET-CT is a functional imaging modality that assesses the metabolic status of tumors. It is valuable for response assessment in the post-treatment setting, and for radiotherapy planning, and has a role in evaluating an unknown primary. It is the best modality form metastatic workup in locally-advanced disease, N2, N3 nodes, advanced T stage, and nasopharyngeal and hypopharyngeal cancers which have a high propensity for distant metastasis [23]. PET-CT is a sensitive technique for the identification of distant metastases as well as occult nodal metastasis and is thus superior to CT/MRI in this aspect. PET-CT also has been proven to be superior to CT and MRI in differentiating post-radiation effects from residual/recurrent disease with sensitivities ranging from 88% to 100% and specificities ranging from 77% to 100% and is the imaging modality of choice for post-therapy surveillance [24]. The strength of the PET-CT, especially in the post-treatment setting lies in its high negative predictive value (NPV) [25].

4.5 Pathology

Squamous cell carcinoma is the most common histological subtype across most of the head neck cancer subsites (oral cavity and laryngopharynx), however, in the nasopharyngeal region, the undifferentiated subtype predominates. Table 2 highlights common histological subtypes encountered across

Table 2 Histological subtypes of head and neck cancer

Nasopharynx
– Keratinizing squamous carcinoma: More common in non-endemic areas (up to 25% cases), no association with EBV.
– Non-keratinizing squamous carcinoma: Uncommon variant (<5% of cases).
– Undifferentiated carcinoma: Commonest histology in the endemic population (up to 90%), strong association with EBV.
– Basaloid carcinoma: a rare variant of squamous carcinoma.
– Others: Adenocarcinoma, adenoid cystic carcinoma, salivary origin carcinoma, and clear cell carcinoma.
Oral cavity
– Squamous cell carcinoma: Predominant subtype (up to 90% of cases).
– Verrucous carcinoma: Warty appearance due to excessive keratinization. Low propensity to nodal metastasis. Good prognosis.
– Basaloid carcinoma: An aggressive high-grade variant with poor prognosis.
– Spindle cell carcinoma: A biphasic tumor with squamous and spindle cell components. Low malignant potential.
– Papillary squamous carcinoma: Exophytic, papillary growth. Distant metastases rare. Associated with a good prognosis.
– Others: Adenosquamous carcinoma, carcinoma cuniculatum, salivary gland tumors, sarcomas, and melanomas.
Oropharynx
– Squamous cell carcinoma: Predominant subtype (up to 90% of cases).
– Other variants: Papillary squamous carcinoma, sarcomatoid squamous carcinoma, and basaloid carcinoma.
– HPV-positive oropharyngeal cancer may be associated with poorly differentiated or basaloid variants.
Larynx and hypopharynx
– Squamous cell carcinoma: Predominant subtype (up to 95% of cases).
– Verrucous carcinoma: Slow growing warty growth. Low malignant potential.
– Others: Basaloid carcinoma, spindle cell variant, lymphomas, and sarcoma.
Nasal cavity and PNS
– Squamous cell carcinoma: Most common malignant tumor (up to 50% cases).
– Salivary gland-type carcinoma: Second most common cancer. Adenoid cystic carcinomas are the most common type, characterized by perineural invasion and extensive bone infiltration. Mucoepidermoid carcinoma, Acinic cell carcinoma, clear cell carcinoma, and myoepithelial carcinoma are other types.
– Adenocarcinoma: Third most common of the malignant tumors. Subclassified into intestinal and non-intestinal types.
– Neuroendocrine tumors: Divided according to the different amounts of neuroendocrine differentiation into well-differentiated (typical), moderately differentiated (atypical carcinoids), and poorly differentiated (small and non-small cell types). Sinonasal undifferentiated carcinoma (SNUC) is a distinct pathological entity with undifferentiated characteristics and varying degrees of positivity to epithelial markers and neuroendocrine markers [26].
– Esthesioneuroblastoma: Arises from the olfactory epithelium. Divided into four different pathological grades (Hyam's system) based on the grade of differentiation, the presence of neurofibrillary stroma, and mitotic figures/necrosis. The grade affects prognosis.
– Others: Melanomas, sarcomas, and lymphomas.

(continued)

Table 2 (continued)

Salivary glands
– Pleomorphic adenoma: Accounts for 75% of benign tumors and 90% occur in the parotids. Malignant transformation was rare, seen in longstanding tumors. – Mucoepidermoid carcinoma: Most common malignant tumor of the major salivary glands. Presents as a slow-growing mass. Histological grade and location predict the clinical behavior. – Adenoid cystic carcinoma: More common in the minor salivary glands. A high grade is associated with a poor prognosis. Characterized by extensive soft tissue infiltration, perineural invasion, and late recurrences. – Adenocarcinoma: Usually seen in the elderly. A high grade is associated with a poor prognosis. In general, the prognosis is worse than most other salivary gland tumors. – Acinic cell carcinoma: Low-grade malignancy, presents as a slow-growing mass. Associated with good prognosis. – Malignant mixed tumors: Carcinoma ex-pleomorphic adenoma is the most common type. Usually seen in the elderly. The prognosis depends on the grade and depth of invasion. – Salivary duct carcinoma: An aggressive tumor. Usually seen in the elderly. Most commonly seen in the parotid gland. High propensity for local recurrence as well as distant metastases. – Others: Epithelial-myoepithelial carcinoma, squamous carcinoma, and small cell carcinoma.

Table 3 Synoptic reporting for head and neck cancer

Specimen details	Macroscopic examination	Microscopic examination
• Anatomic site with laterality • Type of specimen • Biopsy: Incision or excision biopsy • Resection: Type of surgery and neck dissection performed • Received fresh/in formalin • Received intact/fragmented • If the frozen section is sent, then the type of specimen for the frozen section	• Specimen description and size • Location/extent/number/**size and thickness** of tumor foci • **Characteristics of tumor**: Polypoidal/sessile/ulceroproliferative/ulcerative • Gross bone/skin involvement if any • Distance of tumor from mucosal, bony, and soft tissue **cut margins** • Neck nodes: Level/number of nodes dissected with the size of largest node and appearance on the cut surface, extra-nodal spread if any	• **Histological subtype of the tumor** • **Grade/differentiation of the tumor** • **The depth of invasion and patterns of invasion** • **Lymphovascular emboli** • **Perineural invasion** • **Bone/skin involvement** • **Status of the margins** • **Neck nodes**: For each level specify, the number of total nodes dissected, the **number of nodes showing metastasis, and extranodal extension (ENE)** • **p16 expression/HPV status** • Nature of frozen section if sent (closest margin, base, inked margin, node, etc.)

various head-neck subsites. The use of the World Health Organization (WHO) classification system is recommended to avoid confusion. Among the head and neck cancers, pathological examination of sinonasal and salivary gland tumors is one of the most challenging owing to the rarity of the disease, the variety of histological types, a broad spectrum of differentiation among the same histological type, and the presence of overlapping pathological features with other entities.

4.6 Histopathological Examination and Reporting (Synoptic Reporting)

There are some common guidelines for histopathological reporting, despite the diverse sites of origin and complex anatomy. The synoptic reporting style captures these guidelines and at the same time remains concise and user-friendly. This kind of reporting enables focus on histological parameters determining prognosis and influencing adjuvant therapies (highlighted in bold in Table 3).

Table 4 Tumor markers in head and neck cancer

Tumor markers	Role
Plasma/serum EBV copy numbers [27–30]	Play an important role in screening, prognosis, and early detection of relapse of nasopharyngeal carcinoma
EBV antiviral capsid antigen IgA	May have a role in the screening and diagnosis of nasopharyngeal cancer
p16 overexpression and HPV DNA	Marker for HPV-positive oropharyngeal cancer which is associated with improved survival compared to HPV-negative oropharyngeal cancers (82.4% vs 57.1% at 3 years, $p < 0.001$) [16]
Androgen receptors, c-kit, HER-2, p53, and Ki-67	Are being investigated as prognostic markers in salivary gland tumors

4.7 Tumor Markers

Important tumor markers in head and neck cancer are highlighted in Table 4.

4.8 Referrals Including Genetic Counseling

There is an emerging role for this in head and neck cancers, especially for patients with multiple primary neoplasms. However, considering the etiological agents responsible for causation, prevention, lifestyle modification, counseling, and tobacco cessation clinics play a vital role.

5 Principles of Management (an Integrated Brief Overview of Treatment Philosophy)

Treatment decisions for all patients should be made in a multidisciplinary clinic with the goal of maximizing survival while preserving form, function, and quality of life. Factors like age, comorbidity, stage, and performance status play a role in deciding the treatment intent.

Treatment modalities for head-neck cancer include surgery, radiotherapy, and chemotherapy. Radiotherapy can be an external beam, brachytherapy, or a combination of external beam and brachytherapy. Chemotherapy is usually administered prior to definitive modalities like surgery or radiotherapy to reduce the bulk of disease (neoadjuvant chemotherapy or induction chemotherapy) or concurrent with radiotherapy to enhance the effect of radiotherapy (chemoradiotherapy) [31, 32].

6 Surgical Management

For patients undergoing planned surgery, a plan should be developed for a tumor-free resection margin and appropriate reconstruction for the restoration of form and function.

6.1 Assessment of Resectability

Tumor involvement in the following structures is considered technically unresectable:

- Involvement of infratemporal fossa above the level of the sigmoid notch of the mandible.
- Erosion of pterygoid plates, sphenoid bone, widening of foramen ovale.
- Extension to nasopharynx or deep extension into eustachian tube or lateral nasopharyngeal wall.
- Encasement of the internal carotid artery, defined as a tumor surrounding the carotids >270°.
- Involvement of mediastinal structures.
- Involvement of prevertebral fascia or cervical vertebrae.

6.2 Principles of Resection

- **En bloc resection** of primary tumor should be performed whenever feasible
  - The third dimension (the base) should be taken carefully into account before excision.
  - An adequate margin of at least 5 mm should be ensured in all directions.
- A frozen section for confirmation of margins may be done if concerned.
- **Neck dissection** should consist of selective neck dissection (Level I–III in the oral cavity and Level II-IV in the larynx and hypopharynx) in a node-negative neck and a modified radical neck dissection (Level I–V) for a node-positive neck. The contralateral neck should be addressed when the probability of bilateral/contralateral metastases is high, e.g., tumors crossing the midline/midline tumors.

6.3 Reconstruction Options

- Mucosal defects:
  - Small defect: Primary closure/local flap/split-thickness skin graft/leave raw according to the site involved.
  - Large defect: Try to replace tissue loss with similar kinds of tissue using pedicle flaps or free flaps.
- Soft tissue loss:
  - Pedicle flaps, e.g., pectoralis major myocutaneous (PMMC) flap, or free flaps, e.g., free radial artery forearm flap (FRAFF) or anterolateral thigh flap (ALT).
- Skeletal defects ± soft tissue and skin loss:
  - Anterior or midline mandibular defects: Free osteocutaneous flaps, e.g., fibula, scapula, iliac bone, and radius (preferred due to better cosmetic and functional outcome)/plate/pedicle flaps.
  - Posterior segment defects: free fibula flap or a PMMC flap (for small defects) may be used.
- Skin defects:
  - Can be covered with local flaps/forehead flaps/deltopectoral flaps/PMMC/free flaps.

6.4 Rehabilitation

- Abstinence from tobacco/alcohol
- Oral hygiene
- Shoulder and neck physiotherapy in all cases of neck dissections
- Bite guide prosthesis following mandibulectomy
- Jaw stretching exercises to prevent post-operative trismus
- Swallowing and speech rehabilitation
- Ophthalmologic and auditory

7 Medical Management

Cisplatin forms the backbone of head and neck chemotherapy regimens, used exclusively for concurrent regimens along with radiotherapy or used in combination with five fluorouracil (doublet regimen) and a taxane (Triplet regimen) for induction regimen [33, 34] prior to definitive therapy. In patients unfit for cisplatin chemotherapy, cetuximab or nimotuzumab [35], which is an epidermal growth factor receptor (EGFR) inhibitor can be used concurrently with radiotherapy [36] (bio-radiotherapy). Table 5 shows commonly practiced head and neck chemotherapy schedules. Table 6 highlights important trials in head and neck cancer.

Table 5 Head and neck chemotherapy schedule

Neo-adjuvant chemotherapy regimens	
TAX 323 regimen [34]	Docetaxel (75 mg/m^2, Day 1), Cisplatin (75 mg/m^2, Day 1) and 5-FU (750 mg/m^2/day continuous IV infusion, Day 1 to Day 5). Repeated every 3 weeks.
TAX 324 regimen [37]	Docetaxel (75 mg/m^2, Day 1), Cisplatin (100 mg/m^2, Day 1) and 5-FU (1000 mg/m^2/day continuous IV infusion, Day 1 to Day 4). Repeated every 3 weeks.
Sun et al. regimen for nasopharynx [38]	Docetaxel (60 mg/m^2, Day 1), Cisplatin (60 mg/m^2, Day 1), and 5-FU (600 mg/m^2/day continuous IV infusion, Day 1 to Day 5). Repeated every 3 weeks.
Concurrent chemotherapy regimens	
Three weekly cisplatin [39]	100 mg/m^2, once every 3 weeks
Weekly cisplatin	40 mg/m^2 once every week
Weekly cetuximab [36]	400 mg/m^2 initial dose followed by 250 mg/m^2 every week
Weekly nimotuzumab [35]	200 mg every week
Weekly cisplatin + nimotuzumab [35]	40 mg/m^2 cisplatin + 200 mg nimotuzumab every week

Table 6 Important trials in head and neck cancer

S. no.	Author/group	Year	n	Design	Endpoint	Results	Comments
Nasopharynx							
1.	Al-Saraf et al. **INT-0099** [40]	1998	147	Ph III RCT RT vs CTRT + ACT	OS PFS	3 year OS: 47% vs 78% ($p = 0.005$) 3 year PFS: 24% vs 69% ($p < 0.001$)	• Poor compliance • Significant proportion had squamous histology • RT alone arm did very poorly than expected
2.	Sun et al. [38]	2016	480	Ph III RCT CTRT vs ICT + CTRT	FFS	3 year FFS: 72% vs. 80% ($p = 0.034$) 3 year OS: 86% vs. 92% ($p = 0.029$) 3 year DMFS 83% vs. 90% ($p = 0.031$)	• Stage III–IVB (except T3–4N0) patients • All patients received RT with IMRT
Postoperative CTRT							
1.	Cooper et al. **RTOG 95-01** [41]	2004	416	Ph III RCT RT vs CTRT	LRC	2 year LRC: 72% vs. 82% ($p = 0.01$) DFS HR = 0.78 ($p = 0.04$) OS difference is not statistically significant	• Included high-risk patients (two or more positive lymph nodes, or ECE, or positive margins)

(continued)

S. no.	Author/group	Year	n	Design	Endpoint	Results	Comments
2.	Bernier et al. **EORTC 22931** [42]	2004	334	Ph III RCT RT vs CTRT	PFS	5 year PFS: 36% vs 47% ($p = 0.04$) OS 40% vs 53% ($p = 0.02$); LRC 69% vs 82% (SS). No difference in DM rate (21% vs. 25%, NS).	• T3–4 any N with negative margins (except T3N0 of the larynx) • T1–2 N2–3 • T1–2 N0–1 with high-risk features (ECE, positive margins, PNI, LVI) • Oral cavity/oropharynx with LN+ at levels IV or V
3.	Pooled data **RTOG 9501/ EORTC 22931** [32]	2005		Pooled analysis		• ECE and positive margins were the only risk factors that had significant benefits with CTRT. • No other factors (2+ lymph nodes, PNI+, LVI+, stage III–IV disease) showed a statistically significant difference	
Neoadjuvant chemotherapy/induction chemotherapy							
1.	Vermorken et al. **TAX 323** [34]	2007	358	Ph III RCT PF vs TPF, followed by RT/AFRT	PFS	Median PFS 8.2 vs. 11 months ($p = 0.007$) Median OS 14.5 vs. 18.8 months ($p = 0.02$)	• Included stage III/IV unresectable head and neck cancer
2.	Posner et al. **TAX 324** [37]	2007	501	Ph III RCT PF vs TPF, followed by CTRT	OS	Median OS: 2.5 vs. 5.9 years ($p = 0.006$) 3 year OS: 48% vs. 62% ($p = 0.006$).	• Included stage III/IV unresectable head and neck cancer
3.	Blanchard et al. **MACH NC** [43]	2013	1772 5 trials	Meta-analysis NACT-3(TPF) vs 2(PF) drug		• Absolute benefit at 5 years: 7.4% in favor of Tax-PF. • TPF was associated with significant reductions in progression, locoregional failure, and distant failure compared with PF.	
Bio-radiotherapy							
1.	Bonner et al. [36]	2006	424	Ph III RCT Cetuximab + RT/AF vs. RT/AF	LRC	• Median LRC: Cetuximab + RT 24.4 months vs RT alone 14.9 months; 3-year LRC: 47% vs. 34% ($p = 0.005$). • Median PFS: 17.1 vs. 12.4 months; 3-year PFS 42% vs. 31% ($p = 0.006$). • Median survival: Median 4.1 vs. 2.4 years; 3-years OS 55% vs 45% ($p = 0.03$).	
2.	Bonner et al. [44]	2010	424	Ph III RCT Cetuximab + RT/AF vs. RT/AF	LRC	• Primary endpoint (LRC) not reported. • 5-year OS 46% vs 36% ($p = 0.018$). • Survival is significantly better if at least grade 2 skin rash. • On subgroup analysis, a benefit for Cetuximab confined to BID or concomitant boost arms only.	
Meta-analysis defining role of chemotherapy							
1.	Pignon et al. **MACH-NC** [31]	2000	10,741 63 trials	IPD meta-analysis	• Absolute survival benefit of 4% at 2 and 5 years in favor of chemotherapy. • There was no significant benefit associated with adjuvant or NACT. • Significant benefits with concurrent chemo (8%), but the heterogeneity of the results prohibits firm conclusions.		
3.	Pignon et al. **MACH-NC** [45]	2009	17,346 93 trials	IPD meta-analysis	• Absolute benefit for chemotherapy of 4.5% at 5 years. • Both direct and indirect comparisons showed a more pronounced benefit of the concomitant chemotherapy as compared to induction chemotherapy—the absolute benefit 6.5% at 5 years.		
4.	Pignon et al. **MACH-NC** [45]	2009	16,192 87 trials	IPD meta-analysis Analysis by tumor site	• Chemotherapy benefit was higher for concomitant administration for all tumor locations, but the interaction test between chemotherapy timing and treatment effect was only significant for oropharyngeal and laryngeal tumors and not for oral cavity and hypopharyngeal tumors. • The 5-year absolute benefits associated with the concomitant chemotherapy are 8.9%, 8.1%, 5.4%, and 4% for oral cavity, oropharynx, larynx, and hypopharynx tumors, respectively.		

OS overall survival, *FFS* failure-free survival, *PFS* progression-free survival, *DMFS* distant metastases-free survival, *LRC* locoregional control, *HR* hazard ratio, *RCT* randomized control trial, *IPD* individual patient data, *RT* radiotherapy, *CTRT* chemoradiotherapy, *IMRT* intensity-modulated radiotherapy, *ICT* induction chemotherapy, *ACT* adjuvant chemotherapy, *AFRT* accelerated fractionation radiotherapy, *TPF* docetaxel + cisplatin + fluorouracil, *PF* cisplatin + fluorouracil, *ECE* extracapsular extension, *PNI* perineural invasion, *LVI* lymphovascular invasion, *LN+* lymph node-positive

8 Radiation Management

8.1 Definitive Radiotherapy

Radiation therapy is the preferred modality of treatment in the curative setting for cancers of oropharynx, hypopharynx, and larynx where organ conservation is desired and surgical morbidity is too high. In early stages radiation therapy (definitive RT) is used alone and in advanced stages, radiation therapy is combined with concurrent chemotherapy (definitive chemo radiotherapy) to enhance radiation effects or used as an adjuvant to surgery, with or without concurrent chemotherapy. In nasopharyngeal cancer, radiation therapy is the primary treatment modality owing to the radiosensitive nature of the tumor and very morbid/poor results with surgery. Radiation therapy consists of external beam radiotherapy (EBRT) or brachytherapy (BT) or a combination of both (EBRT + BT) (Table 7).

Doses and volumes in the definitive EBRT setting:

- Primary and involved nodal stations should receive 66–70 Gy equivalent and uninvolved nodes 45–50 Gy.
- Dose/fractionation: 66–70 Gy/33–35 fractions/7 weeks (5 fractions per week). The most commonly used dose-fractionation for RT alone or chemo-radiation. Various other forms of fractionation like accelerated fractionation hyper-fractionation [53] have also been described.
- The dose of cisplatin for chemo-radiotherapy in advanced stages (stage III/IV): Cisplatin 40 mg/m^2 weekly or 100 mg/m^2 every 3 weeks (day 1, 22 and 43) during RT, with hydration and antiemetic prophylaxis.
- The dose of cetuximab for bio-radiotherapy in advanced stage (stage III/IV) patients not fit for cisplatin chemotherapy: 400 mg/m^2 loading dose over 120 min, 1 week prior to commencing radiotherapy, then 250 mg/m^2 weekly during radiotherapy.
- The dose of nimotuzumab for bio-radiotherapy in advanced stage (stage III/IV) patients: 200 mg every weekly. Nimotuzumab can be given as monotherapy in patients not fit or cisplatin along with cisplatin in patients that are fit.

8.2 Brachytherapy

Brachytherapy is a technique of radiotherapy in which radiation sources are placed in or around the tumor. It can be used as a sole modality for definitive RT in the selected early-stage tumor, where the risk of LN involvement is low, or in combination with EBRT to boost the tumor to a higher dose,

Table 7 Important trials in larynx and hypopharynx

S. no.	Author/group	Year	*n*	Design	Endpoint	Results	Comments
1.	Wolf et al. [46] **VA LARYNX TRIAL**	1991	332	Ph III RCT Total laryngectomy + postop RT vs. induction chemo + RT	OS	2-year OS: 68% vs 68% ($p = 0.984$) Larynx preservation: Overall 64%.	– Demonstrated that organ conservation is possible in a significant proportion of patients without affecting survival. – More recurrence at the primary site (12% vs 2%) in the chemo/RT group vs more distant metastases in the surgery group (17% vs 11%).
2.	Lefebvre et al. [47] **EORTC 24891**	2004	202	Ph III RCT Surgery + post-op RT vs induction cisplatin/5-FU + RT	OS	5-year OS 33% vs. 38% 10-year OS 14% vs. 13% 5-year PFS 26% vs. 32%. Larynx preservation 5 years 22%	– This strategy did not compromise disease control or survival (that remained poor) and allowed more than half of the survivors to retain their larynx.
3.	Forastiere et al. [48] **RTOG 9111**	2003	547	Ph III RCT Sequential chemo-RT vs. concurrent chemo-RT vs. RT alone	LP	Larynx preservation: 71% vs. 84% vs. 66% ($p = 0.0001$). Laryngectomy-free survival at 2 years and 5 years—no significant difference ($p = 0.98$) between the two chemo groups but a significant difference between chemo arms and RT alone ($p = 0.011$). No difference in 2 years/5 years OS; distant metastases reduced by chemotherapy	Induction PF followed by RT and CT/RT show similar efficacy for the composite endpoint of LFS. Locoregional control and larynx preservation were significantly improved with concomitant cisplatin/RT compared with the induction arm or RT alone.

(continued)

Table 7 (continued)

S. no.	Author/group	Year	*n*	Design	Endpoint	Results	Comments
4.	Forastiere et al. [49] **RTOG 9111**	2012 10 year update		RCT Sequential chemo-RT vs. concurrent chemo-RT vs. RT alone		10 year update • Chemo arms had significantly higher LFS (laryngectomy-free survival) compared to RT alone arm ($p = 0.03$). No difference in LFS between the two chemo arms. Induction (28.9%) = CTRT arm (23.5%) > RT alone (17.2%). • CTRT arm significantly improved laryngeal preservation rate compared to induction ($p = 0.005$) and RT alone arm ($p < 0.001$). No significant difference between induction and RT alone. CTRT (81%), >induction (67%) = RT alone (63%). • Distant control: Induction (83%), concomitant (83%) > RT alone (76%) for distant control.	
5.	Vermorken et al. **TAX 323** [34]	2007	358	Ph III RCT PF vs TPF, followed by RT/AFRT	PFS	Median PFS 8.2 vs. 11 months ($p = 0.007$) Median OS 14.5 vs. 18.8 months ($p = 0.02$)	Including stage III/IV unresectable head and neck cancer. No comparison with CTRT alone, which is the standard.
6.	Posner et al. **TAX 324** [37]	2007	501	Ph III RCT PF vs TPF, followed by CTRT	OS	Median OS: 2.5 vs. 5.9 years ($p = 0.006$) 3 year OS: 48% vs. 62%, ($p = 0.006$)	Including stage III/IV unresectable head and neck cancer. No comparison with CTRT alone, which is the standard.
7.	Haddad et al. [50] **PARADIGM**	2013	145	Ph III RCT TPF, followed by CTRT vs. CTRT alone	OS	3 Year OS: 73% vs 78% ($p = 0.77$)	Upfront chemoradiation remains the standard of care over induction chemotherapy followed by chemoradiation
Altered fractionation trials							
1.	Overgaard et al. [51] **IAEA-ACC**	2010 Lancet	1008	PH III RCT 5 vs 6 day RT	LRC	5 Years LRC were 30% vs 42% ($p = 0.004$)	A trend toward OS benefit Higher acute toxicities with 6 day RT No increase in late toxicity
2.	Overgaard et al. [52] **DAHANCA 6&7**	2003 Lancet	1485	PH III RCT 5 vs 6 day RT	LRC	5-year LRC 60% vs 70% ($p = 0.0005$). DFS improved (66% vs 73%, $p = 0.01$) but not overall survival.	The benefit was seen for primary tumor control but not nodes. Improved larynx preservation by 80% vs 68%. Increased acute morbidity for the 6-week treatment.
3.	Fu et al. [53] **RTOG 90-03**	2000/2005	1073	SFRT vs HFRT vs Split course AFRT vs AFRT-CB	LRC	HFRT or CB improve LRC ($p = 0.045$ and $p = 0.05$) compared to SFRT A trend for a better OS with HF.	Increased acute effects with all 3. AFX-CB may lead to more grade 3+ late effects.
4.	Bourhis et al. [54] **MARCH**	2006	6515 15 trials	Meta-analysis	Significant survival benefit with altered fractionation, corresponding to an absolute benefit of 3.4% at 5 years ($p = 0.003$). Benefit significantly higher with HF (8% at 5 years) than with AFRT (2% without total dose reduction and 1.7% with total dose reduction at 5 years, $p = 0.02$). There was a benefit on LRC in favor of altered fractionation (6.4% at 5 years; $p < 0.0001$), which was particularly efficient in reducing local failure, than on nodal control.		

OS overall survival, *PFS* progression-free survival, *DMFS* distant metastases, free survival, *LRC* locoregional control, *HR* hazard ratio, *RCT* randomized control trial, *IPD* individual patient data, *RT* radiotherapy, *CTRT* chemoradiotherapy, *ICT* induction chemotherapy, *ACT* adjuvant chemotherapy, *SFRT* standard fractionation RT, *HFRT* hyper-fractionated RT, *AFRT* accelerated fractionation radiotherapy, *CB* concomitant boost, *TPF* docetaxel + cisplatin + fluorouracil, *PF* cisplatin + fluorouracil

to enhance local control. It can also serve as a salvage option in small-volume recurrent disease in combination with surgery or as a lone treatment option.

Lesions suitable for radical brachytherapy include accessible lesions, Small (preferably <3 cm) tumors, Lesions away from the bone, N0 nodal status, and superficial lesions.

Doses used in the brachytherapy setting:

- Radical BT (for T1–T2, N0): 60–70 Gy low dose rate with Iridium-192 or equivalent doses with fractionated high dose rate (e.g., 52 Gy in 13 fractions over 6 days at 4 Gy per fraction b.i.d).

Table 8 Indications for postoperative/adjuvant radiotherapy

Primary	Lymph nodes	Chemo-radiotherapy [32]
– Large primary (pT3/T4) – High-grade tumor – Close/positive margins Relative indications: – Deep infiltrative tumor (DOI) – Lymphovascular invasion (LVE) – Perineural invasion (PNI)	– Bulky nodal disease N2/N3 – Extranodal extension – Multiple-level involvement – Multiple nodes	– Positive resection margin – Extranodal extension (ENE)

- In combination with EBRT (for T1–T3, N0–1): external RT to a dose of 56–60 Gy/28–30#/6 weeks followed by BT boost of 15–20 Gy, low-dose rate, Iridium-192 or 14 Gy in 4 fractions high-dose rate over 2 days (4–3–3–4 Gy).

8.3 Adjuvant Radiotherapy

In other sites like the oral cavity, paranasal sinuses, and salivary glands, where surgery is the preferred modality radiation therapy is used in the adjuvant setting with or without chemotherapy to improve local control and survival. Indications of adjuvant radiotherapy are given in Table 8.

Doses and volumes in the adjuvant setting:

- Primary and involved nodal disease: 56–60 Gy/28–30#/6 weeks, using reducing fields.
- In the presence of R+ resection, site of residual disease, positive cut margins, and ENE: 4–6 Gy boost [55].
- Uninvolved nodal stations: 50 Gy/25#, equivalent.
- The dose of chemotherapy [39] in the adjuvant setting in combination with radiotherapy: Cisplatin 40 mg/m^2 weekly or 100 mg/m^2 every 3 weeks (days 1, 22, and 43) during RT, with hydration and antiemetic prophylaxis.
- Postoperative RT should commence as soon as possible and preferably within 6 weeks. Overall treatment time (OTT) should be kept within 100 days, as prolonged OTT is associated with inferior survival.

9 Site-Wise Management Algorithms

9.1 Nasopharyngeal Cancer

Nasopharyngeal carcinomas are relatively radio and chemosensitive tumors.

Radiotherapy forms the mainstay of treatment of nasopharyngeal carcinomas. Surgery has a very limited role to play in the management of nasopharyngeal carcinomas. Chemotherapy [40] in combination with radiotherapy has been shown to improve survival in advanced nasopharyngeal carcinomas. However, there has been a lack of consensus regarding the optimal sequencing of chemotherapy with radiotherapy.

An earlier meta-analysis [56] showed that concurrent chemoradiation (CTRT) definitely contributes the most towards disease control. However, a significant proportion (22% at 3 years) of patients develop distant metastases after concurrent CTRT necessitating intensification of systemic treatment. Owing to poor compliance (60%) to adjuvant chemotherapy (ACT) after chemoradiation, induction chemotherapy (ICT) is emerging as a preferred means of treatment intensification. Phase II studies have shown good compliance (90%) to ICT with the ability to attain higher doses of the systemic agents and could result in better eradication of distant micro-metastases. A recent randomized trial [38] of induction chemotherapy has shown a survival benefit with the addition of induction chemotherapy to standard CTRT. However, there has been no direct comparison with CTRT followed by the ACT, which is considered the standard of care in some parts. Induction chemotherapy and concurrent chemotherapy schedules are highlighted in Table 6.

With respect to radiotherapy techniques, the current IMRT series enjoy a 3-year locoregional control of over 90% and compared to the 2D technique, IMRT is associated with improvement in local control (especially for late T-stages), Survival [57], and lower incidence of late toxicities (especially delayed xerostomia and late neurological toxicities). Thus, IMRT is the standard treatment technique for NPC.

9.2 Target Volumes and Doses

Target volumes for NPC are based on strong knowledge of patterns of tumor spread as well as patterns of failure. Traditionally, in the 2D era, it extended from the sphenoid sinus superiorly to the clavicle inferiorly, anteriorly including a posterior third of nasal cavity/maxilla, and posteriorly including level V lymph nodes. Contouring target volumes for NPC are derived from these 2D volumes.

9.3 Delineation of GTV

CT, MRI, and PET CT are good imaging modalities for the delineation of GTV. MRI is superior to CT in delineating muscle/soft tissue involvement, and infiltration of the skull base. PET-CT is superior to CT/MRI in the detection of occult nodal/distant metastases; however, underestimates tumors at skull base and cavernous sinuses due to lower resolution compared with MRI. MRI remains the modality of choice for tumor extent delineation. The delineation technique of clinical target volume (CTV) for nasopharyngeal cancer is highlighted in Table 9.

Alternatively, only a high-risk and a low-risk CTV may also be contoured, wherein high-risk CTV and intermediate-risk CTV may be contoured as one single dose level. PTV margins depend on institutional practice. Setup and treatment-related factors influence PTV margins.

Table 9 CTV delineation and doses for nasopharyngeal cancer [58]

High-risk CTV	Gross disease with adequate margins (primary + nodes)	**70 Gy/33#** or 66 Gy/30# or 70 Gy/35#
Intermediate risk CTV	High-risk subclinical region—entire nasopharynx, retropharyngeal nodes, skull base, clivus, pterygoid fossae, PPS, sphenoid sinus, posterior 1/3 nasal cavity and maxillary sinuses to include the pterygopalatine fossae	**59.4 Gy/33#** or 60 Gy/30# or 63 Gy/35#
Low-risk CTV	Uninvolved nodal levels B/L level II–V (level I may not be treated if uninvolved)	**54 Gy/33#** or 54 Gy/30# or 56 Gy/35#

9.4 Management Algorithm for Nasopharyngeal Cancer

Treatment of NPC depends on the stage of the disease (which can be found in AJCC Cancer Staging Manual, Eighth Edition, Page no. 107–108, Chapter no. 9, Nasophyarynx, Table: Definition of TNM and AJCC prognostic stage groups and which can be accessed at https://emedicine.medscape.com/article/2048007-overview and Table 10). Radiation alone (IMRT) for stages I and II, and CTRT ± ACT or ICT + CTRT for stages III–IVB diseases is currently considered the standard of care for the management of NPC.

9.5 Oral Cavity

Early-stage oral cavity cancers are typically managed with single-modality therapy (surgery or radiotherapy), while advanced stages are managed with a multimodality approach. Surgery is the preferred modality for resectable, oral cavity cancers; expect early lesions on the lip, angle of mouth, and hard palate. The treatment philosophy behind the selection of one modality over the other has been described in detail in Fig. 1.

Table 10 Management algorithm for nasopharyngeal cancer

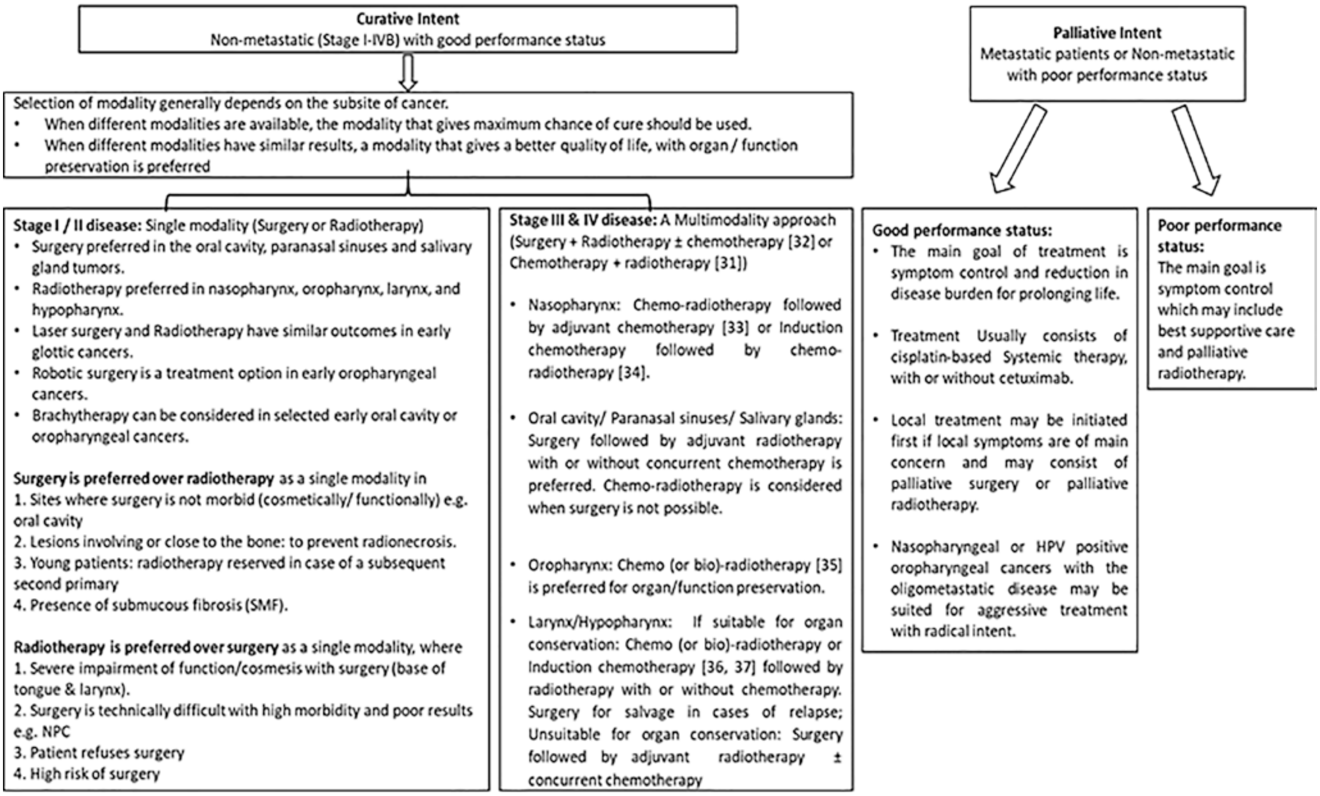
– Palliative radiotherapy may be offered to the symptomatic metastatic site or for palliation of progressive locoregional disease</td></tr>
<tr><td colspan="4">Follow-up
– Nasopharyngoscopy and imaging exam (MRI, PET-CT) 12–16 weeks post-RT to evaluate the response
– Follow-up should include an examination of the nasopharynx and neck, cranial nerve function, and evaluation of systemic complaints to identify distant metastasis
– For T3 and T4 tumors, PET-CT/MRI might be used on a yearly basis for at least 5 years
– Evaluation of hormonal function is recommended annually</td></tr>
</table>



Curative Intent
Non-metastatic (Stage I-IVB) with good performance status

Selection of modality generally depends on the subsite of cancer.
- When different modalities are available, the modality that gives maximum chance of cure should be used.
- When different modalities have similar results, a modality that gives a better quality of life, with organ / function preservation is preferred

Stage I / II disease: Single modality (Surgery or Radiotherapy)
- Surgery preferred in the oral cavity, paranasal sinuses and salivary gland tumors.
- Radiotherapy preferred in nasopharynx, oropharynx, larynx, and hypopharynx.
- Laser surgery and Radiotherapy have similar outcomes in early glottic cancers.
- Robotic surgery is a treatment option in early oropharyngeal cancers.
- Brachytherapy can be considered in selected early oral cavity or oropharyngeal cancers.

Surgery is preferred over radiotherapy as a single modality in
1. Sites where surgery is not morbid (cosmetically/ functionally) e.g. oral cavity
2. Lesions involving or close to the bone: to prevent radionecrosis.
3. Young patients: radiotherapy reserved in case of a subsequent second primary
4. Presence of submucous fibrosis (SMF).

Radiotherapy is preferred over surgery as a single modality, where
1. Severe impairment of function/cosmesis with surgery (base of tongue & larynx).
2. Surgery is technically difficult with high morbidity and poor results e.g. NPC
3. Patient refuses surgery
4. High risk of surgery

Stage III & IV disease: A Multimodality approach (Surgery + Radiotherapy ± chemotherapy [32] or Chemotherapy + radiotherapy [31])
- Nasopharynx: Chemo-radiotherapy followed by adjuvant chemotherapy [33] or Induction chemotherapy followed by chemo-radiotherapy [34].
- Oral cavity/ Paranasal sinuses/ Salivary glands: Surgery followed by adjuvant radiotherapy with or without concurrent chemotherapy is preferred. Chemo-radiotherapy is considered when surgery is not possible.
- Oropharynx: Chemo (or bio)-radiotherapy [35] is preferred for organ/function preservation.
- Larynx/Hypopharynx: If suitable for organ conservation: Chemo (or bio)-radiotherapy or Induction chemotherapy [36, 37] followed by radiotherapy with or without chemotherapy. Surgery for salvage in cases of relapse; Unsuitable for organ conservation: Surgery followed by adjuvant radiotherapy ± concurrent chemotherapy

Palliative Intent
Metastatic patients or Non-metastatic with poor performance status

Good performance status:
- The main goal of treatment is symptom control and reduction in disease burden for prolonging life.
- Treatment Usually consists of cisplatin-based Systemic therapy, with or without cetuximab.
- Local treatment may be initiated first if local symptoms are of main concern and may consist of palliative surgery or palliative radiotherapy.
- Nasopharyngeal or HPV positive oropharyngeal cancers with the oligometastatic disease may be suited for aggressive treatment with radical intent.

Poor performance status:
The main goal is symptom control which may include best supportive care and palliative radiotherapy.

Fig. 1 Treatment philosophy and general overview

Resectable cancers are generally treated with surgery ± postoperative radiotherapy/chemo-radiotherapy. The decision regarding adjuvant therapy is usually based on a number of histological parameters previously described in Table 8. The role of intensified treatment for other high-risk factors (lymphovascular invasion, perineural invasion, larger and deeper tumors) needs to be established. Locally advanced tumors involving the masticator space, encasing the carotids, or infiltrating the prevertebral muscles are generally unresectable and are usually managed with chemo-radiotherapy or in certain selected cases Neoadjuvant chemotherapy may be used to shrink the tumor and attempt curative surgery. Staging can be found in AJCC Cancer Staging Manual, Eighth Edition, Page no. 90–91, Chapter no. 7, Lip and oral cavity, Table: Definition of TNM and AJCC Prognostic Stage Groups which can be accessed at https://emedicine.medscape.com/article/2048034-overview and Table 11 highlights the treatment algorithm for oral cavity cancers. Adjuvant radiotherapy/chemo-radiotherapy indications, radiotherapy doses, chemotherapy schedules, and reconstructive options have been described previously.

9.5.1 Oropharynx

The treatment of oropharyngeal carcinoma is aimed at maximizing cure with minimal functional morbidity. Radical radiotherapy is the treatment of choice in early T1, and T2 tumors, and chemo radiotherapy is the treatment of choice in advanced T3, and T4 tumors. IMRT is the preferred modality of radiotherapy for tumors of the Oropharynx. Surgery is preferred in select early cases where surgical resection is associated with reasonable functional outcomes. It is also preferred with postoperative radiotherapy in select advanced cases, e.g. infiltrative lesions of the base tongue, tonsil, and lesions involving the mandible, and as a salvage procedure for residual neck nodes following chemoradiotherapy.

Transoral resection and neck dissection ± postoperative radiotherapy is gaining popularity for early-stage oropharyngeal cancer especially more so in the HPV-positive setting. Transoral surgery is preferable to open surgery due to lower morbidity and improved function preservation. Various TORS series [59] have reported improved functional outcomes compared to the RT series with this strategy. However, patients with Positive surgical margins and extranodal extension require adjuvant CTRT and Positive margin status can be quite high [60] in some of the series thereby exposing patients to side effects of multiple treatment modalities.

Oropharyngeal primaries have a high predilection for neck node metastases and therefore almost always require elective treatment of cervical lymph node regions at risk of involvement. For the elective treatment of the neck in cN0 patients, irradiation of at least level II-IV is recommended. Elective treatment of the neck usually includes the bilateral

Table 11 Management algorithm for oral cavity cancer

Staging workup • Detailed clinical examination • Examination under anesthesia if the clinical exam is difficult • USG neck for N0 neck • CT scan for the local extent and bone invasion in gingivobuccal complex tumors • MRI is preferred for the tongue and floor of the mouth and for extension in the oropharynx or parapharyngeal space			**Other workup** • Dental prophylaxis • Nutritional counseling • Speech and swallowing evaluation • PET-CT in recurrent case
Treatment algorithm			
Stage I (T1 N0)	**Stage II (T2 N0)**	**Stage III–IVB (T3–T4 N0 or any T N+)**	**Stage IVC (any T any N M1)**
Single-modality therapy: Surgery or RT – Surgery is preferred as it does not involve significant cosmetic/functional deficits. – Radiotherapy is reserved for cases of second primary. – Brachytherapy is a viable option in feasible cases.		Resectable cases: Surgery + adjuvant RT ± chemotherapy with appropriate reconstruction. Unresectable disease: CTRT or induction chemotherapy followed by reassessment for surgery. If the patient is unable to tolerate CTRT, palliative treatment for symptom relief.	– Individualized treatment depending on symptoms. – Palliative radiotherapy may be offered to control loco regional symptoms or for the skeletal metastatic site. – Platinum-based doublet or triplet chemotherapy should be used as the first line systemic therapy in patients with good performance status. – Best supportive care.
Follow-up – Detailed history and clinical examination on each follow-up. – Follow up every 2–3 months for the first 2 years, every 4–6 months for the next 3 years, and annually thereafter. – Rehabilitation: Jaw stretching exercises, dental evaluation, speech, and swallowing therapy. – Routine CT/MRI scans are not recommended: Imaging for suspected locoregional recurrence to assess the feasibility of salvage. – PET-CT scan for suspected, non-accessible recurrences and to rule out distant metastasis. – Biopsy confirmation.			

neck; however, unilateral irradiation [61] may be considered in the well-lateralized tonsillar primary with ≤1 cm mucosal involvement of the base of the tongue or soft palate and N0–N1 nodal status.

PET-CT is the preferred modality for response assessment after chemoradiotherapy with a very high NPV for neck nodes and a moderate NPV for the primary. Patients with a complete response to PET-CT can be kept under surveillance [10].

HPV-positive tumors have improved survival compared to HPV-negative tumors; therefore, several clinical trials are underway, evaluating deintensification strategies in HPV-positive oropharyngeal cancers. However, currently, no difference in treatment recommendations exists, between HPV-negative and HPV-positive tumors.

Staging can be found in AJCC Cancer Staging Manual, Eighth Edition, Page no. 120, 128–130, Chapter no. 10, HPV-Mediated (p16+) Oropharyngeal Cancer and 11, Oropharynx (p16-) and Hypopharynx Table: Definition of TNM and AJCC prognostic staging groups and which can be accessed at https://emedicine.medscape.com/article/2048285-overview. Table 12 highlights the treatment algorithm for oropharyngeal cancers.

9.5.2 Larynx and Hypopharynx

The management of larynx and hypopharyngeal cancers has seen more changes than any other site amongst head and neck tumors. Since 1991, when the first randomized controlled trial [46] comparing organ preservation versus the gold standard of total laryngectomy in advanced laryngopharyngeal cancers was published, the standards of care have constantly evolved in the past two decades.

Along the way, conservative laryngeal surgery took a new dimension with the acceptance of transoral laryngeal microsurgery as an established treatment option in early laryngopharyngeal cancers. For intermediate-advanced diseases, supracricoid laryngectomy has shown promising results.

In the past 5 years, taxane-based chemotherapy [34, 37] and biological modifiers such as cetuximab [36] and nimotuzumab have improved response rates bringing more moderately advanced laryngopharyngeal cancers into the realm of organ preservation. New technology and altered fractionation regimes have allowed the delivery of optimal radiation dosage and reduced toxicities and morbidity to patients. With the availability of so many treatment options, it is important to evaluate every patient in a multidisciplinary team to decide on the optimal treatment.

For early cancers, both surgery and RT are equally good options for disease control, and the choice of one over the other is essentially driven by the availability of resources and expertise, patient preferences, associated morbidity, and the chance of function preservation or recovery. Laser microsurgery has the advantage of completing the treatment in a single setting and is very effective in very small tumors, however, with larger tumors (e.g., involving both cords), early voice quality may be better with RT.

Table 12 Management algorithm for oropharyngeal cancer

<tr><td>Stage I–II</td><td>Stage III–IVB</td><td>Stage IVC, metastatic OPC</td></tr>
<tr><td>• Radical radiotherapy:
– EBRT alone: In most cases. Primary tumor to a dose of 70 Gy/35 fractions or equivalent, low-risk nodal region to 50 Gy equivalent.
– Radical BT: Selected accessible T1 tumors of the soft palate and Tonsil, 50–60 Gy LDR equivalent.
– EBRT + BT: Bulky T2 tumors and BOT tumors, 46–50 Gy EBRT to primary and neck + 20–30 Gy LDR boost.
• Transoral surgery: In selected cases.</td><td>– Chemoradiotherapy.
– Accelerated radiotherapy ± cetuximab if unsuitable for CTRT.
– Primary tumor to a dose of 70 Gy/35 fractions or equivalent, low-risk nodal region to 50 Gy equivalent.
– Surgery reserved for salvage setting.</td><td>– Symptom control and supportive care.
– Palliative radiotherapy may be offered to control loco regional symptoms or for the skeletal metastatic site.
– Platinum-based doublet or triplet chemotherapy should be used as the first line systemic therapy in patients with good performance status.
– HPV-positive patients with oligometastatic disease and good performance status may be treated with more aggressive measures.</td></tr>
<tr><td colspan="3">Follow-up
– Assessment of treatment response with PET-CT at 12–16 weeks.
– Radiological local/nodal residual disease: If biopsy positive and resectable: Salvage surgery or salvage neck dissection. If biopsy positive and unresectable: Palliative chemotherapy. If biopsy negative: Continue follow-up or repeat biopsy if necessary.
– Clinico radiological complete response: Follow up every 2–3 months for the first 2 years, every 4–6 months for the next 3 years, and annually thereafter.
– Routine CT/MRI scans are not recommended: Imaging for suspected locoregional recurrence to assess the feasibility of salvage.
– PET-CT scan for suspected, non-accessible recurrences and to rule out distant metastasis.
– Dental evaluation, speech and swallowing evaluation, audiometry, and thyroid function on follow-up.</td></tr>
</table>

The intermediate-advanced disease is usually treated with a multimodality approach, organ conservation protocols, and non-surgical organ conservation using radiation therapy with chemo/biological therapy or altered fractionation is preferred in most.

Gross cartilage erosion and dysfunctional larynx need to be ruled out in patients being considered for organ conservation strategies.

Resectable cancers are not fit for organ conservation due to gross cartilage erosion or dysfunctional larynx are managed with a total laryngectomy ± pharyngectomy ± esophagectomy and bilateral neck dissection (clearance of levels II-IV in N0 neck and MND in N+ neck) depending on the extent of disease. This needs to be followed by appropriate pharyngeal reconstruction (Folded PMMC or FRAFF ± gastric pull-up are used) as well as voice rehabilitation. Tracheoesophageal speech gives the best voice outcome after total laryngectomy. Tracheoesophageal puncture is preferably performed at primary surgery. Other options include esophageal speech and electrolarynx.

Unresectable cancers are typically managed with chemoradiotherapy ± salvage surgery or Induction chemotherapy followed by reassessment for surgery or CTRT. Induction chemotherapy also plays a role in locally advanced resectable cancers by selecting patients that may benefit from organ conservation. Patients with a complete or partial response after induction chemotherapy warrant radical chemo-radiotherapy as for early disease, while patients with stable disease or progression of disease should preferably be treated with surgery.

Table 6 highlights important trials of organ conservation in the larynx and pharynx. The staging of laryngeal and hypopharyngeal cancer can be found in AJCC Cancer Staging Manual, Eighth Edition, Page no. 129, 130, 155, and 156, Chapter no. 11; Oropharynx (p16-) and Hypopharynx and Chapter no. 13 Larynx, Table: Definition of TNM staging and AJCC prognostic staging groups and which can be accessed at https://emedicine.medscape.com/article/2048285-overview and https://emedicine.medscape.com/article/2048034-overview and Table 13 shows the treatment algorithm.

(continued)

Table 13 (continued)

Locally-advanced unresectable disease (T4b any N)	**Metastatic**

• Concurrent CTRT
• Induction chemotherapy is an option in patients with good performance status; followed by response assessment:
  – Partial response: concurrent CRT/radical RT
  – Progressive disease: palliative treatment
• Palliative radiotherapy/chemotherapy or BSC in poor performance status
	– Symptom control and supportive care
	– Palliative radiotherapy may be offered to control loco regional symptoms or for the skeletal metastatic site
	– Palliative chemotherapy in patients with good performance status (platinum + 5-FU + cetuximab; alternatives are platinum doublets with 5-FU or a taxane)
	– Best supportive care in patients with poor performance status

Follow-up Post-organ conservation protocols: – Assessment of treatment response with PET-CT at 12–16 weeks. – **Radiological local/nodal residual disease**: If biopsy positive and Resectable: Salvage surgery or salvage neck dissection. If biopsy positive and Unresectable: Palliative chemotherapy. If biopsy negative: Continue follow-up or repeat biopsy if necessary. – **Clinico radiological complete response**: Follow up every 2–3 months for the first 2 years, every 4–6 months for the next 3 years, and annually thereafter. – Routine CT/MRI scans are not recommended: Imaging for suspected locoregional recurrence to assess the feasibility of salvage. – PET-CT scan for suspected, non-accessible recurrences and to rule out distant metastasis. – Dental evaluation, speech, and swallowing rehabilitation, audiometry and thyroid function on follow-up.	

Neck dissection extent, adjuvant therapies (indications and doses), reconstruction, and rehabilitation as described previously in the previous sections of surgical, medical, and radiation management

CTRT chemo-radiotherapy, *AFRT* accelerated fractionation RT, *ND* neck dissection

9.6 Nasal Cavity and Paranasal Sinuses

Sinonasal malignancies are relatively less common cancers, accounting for <5% of all head-neck malignancies. They are a heterogeneous group of lesions with different sites originating from different histopathologic components. This heterogeneity and the small numbers in each group make it difficult to obtain a high level of evidence in their management.

Newer advances in surgery and radiotherapy have improved survival in these cancers. There is an increasing role of endoscopy in the surgical management of these cases. The standard of care for the treatment of malignancies of the paranasal sinus is craniofacial resection. However, recently the role of endoscopic endonasal resection in the management of these tumors has come to the fore. The endoscopic techniques whether endonasal alone in case of limited disease or combined with open craniotomy have shown encouraging oncological results which are comparable or better to open craniofacial approaches, with significantly reduced morbidity and hospital stay. However, there are definite limitations to the endoscopic approaches.

Absolute contraindications for endoscopic resection:

- Skin involvement
- The anterior wall of maxilla
- Gross brain invasion
- Involvement of the floor of the nasal cavity
- Involvement of lateral or posterior nasopharyngeal walls
- Involvement of the lateral wall of maxilla
- Involvement of the posterior wall of the frontal sinus

In addition, it is imperative that surgeons, who are well-versed and competent with both endoscopic as well as open-surgical approaches, carry out endoscopic resections. Appropriate multilayer reconstruction of the dural defects should be carried out.

Orbital preservation can be attempted in certain cases where there is no invasion of the orbital fat, intraorbital muscles, or orbital apex. One way to plan orbital preservation is to biopsy the orbital fat near the tumor and preserve the orbit only if the fat is negative for tumor infiltration on the frozen section. However, in case of any doubt, it may be oncologically prudent to resect the orbit.

Post-operative radiotherapy is usually indicated in patients with T3–4 tumors, the involvement of adjacent structures like bone, dura, and brain, compromised surgical margins, the presence of lymphovascular invasion, perineural invasion, and positive lymph nodes with or without the extracapsular spread. A dose of 56–60 Gy in patients with a negative margin and 64–66 Gy in patients with positive margins are required. Critical structures surrounding the PNS may limit the delivery of these doses; however, the advent of IMRT with image guidance has definitely improved the dose delivery to these tumors.

Inoperable tumors are typically managed by CTRT or RT alone. Distant metastasis is managed with palliative intent with either chemotherapy or palliative RT to symptomatic sites or best supportive care (BSC) in those with poor performance status.

Neoadjuvant chemotherapy may benefit patients with borderline resectable cases and selected unresectable cases. It is also utilized as an attempt for orbital preservation in selected cases. Cisplatin forms the backbone of neoadjuvant chemotherapy and is combined with different drugs depending upon histology: combination with 5-fluorouracil (5-FU) for ITAC; VP-16 for sinonasal tumors with a neuroendocrine component; doxorubicin for salivary gland tumors; and taxanes and 5-FU for squamous histology. Staging can be found in AJCC Cancer Staging Manual, Eighth Edition, Page no. 142–143, Chapter no. 12: Nasal Cavity and Paranasal Sinuses, Table: Definition of TNM and AJCC prognostic stage groups which can be accessed at https://emedicine.medscape.com/article/2047703-overview and Table 14 highlights treatment algorithm for nasal cavity and paranasal sinus cancers.

Table 14 Management algorithm for paranasal sinuses

Staging workup • Detailed endoscopic examination and biopsy • CT scan—preferred for osseous involvement, the floor of the anterior cranial fossa, and orbital walls • MRI preferred for an intracranial extension, perineural spread, post-surgery setting, differentiation between retained secretions and tumor tissue • PET-CT to rule out distant metastases in patients with aggressive histologies and high-grade tumors	**Other workup** • Dental prophylaxis • Ophthalmological evaluation • Endocrine evaluation	
Treatment algorithm nasal cavity and ethmoid sinuses		
T1–T2	**T3–T4a**	**T4b**
• Surgery ± post-operative radiotherapy – Approaches: Midfacial degloving or lateral rhinotomy or endoscopic transnasal – Medial maxillectomy with ethmoidal clearance may be adequate for localized ethmoidal and nasal cavity tumors – Neck dissection in N+ neck – RT in case of margin positivity or perineural spread. Dose: 54–60 Gy • Radical radiotherapy preferred if surgical resection is morbid/patients are unfit or unwilling for surgery. Dose: 60–66 Gy.	• Surgery + adjuvant RT (concurrent chemo as per Indication) – Total Maxillectomy with ethmoidectomy – Combined craniofacial approach for lesions reaching/involving the cribriform plate – Orbital exenteration if eye involved – Neck dissection in N+ neck	– Concurrent CTRT – Resection in a very select group with favorable histology with low biologically aggressive tumors for, e.g. adenoid cystic carcinoma, basal cell carcinoma – Neck dissection in N+ neck – Poor PS: Best supportive care
Treatment algorithm maxillary sinuses		
T1–T2	**T3–T4a**	**T4b**
• Surgery + post-op radiotherapy – Infrastructure maxillectomy – Maxillectomy with orbital plate preservation – RT in case of margin positivity or perineural spread or adenoid cystic histology – Neck dissection in N+ neck	• Surgery (primary and neck) + post-op RT (concurrent chemo as per indication) – Total maxillectomy with ethmoidectomy in T3 – Combined craniofacial resection in T4 – Orbital exenteration if eye involved – NACT can be considered if orbital preservation to be attempted or in borderline resectable cases	– Concurrent CTRT – Resection in a very select group with favorable histology with low biologically aggressive tumors for, e.g. adenoid cystic carcinoma, basal cell carcinoma – Poor PS: best supportive care
Post-maxillectomy reconstruction: – If palatal defect is less than one-third: obturator preferred. – Sling if orbital floor excised, to prevent post-op diplopia. Fascial sling is preferred over muscle. Titanium mesh may be used. – Microvascular free tissue transfer for • Extensive skin and soft tissue defect • More than half of palatal loss • Orbit resection • Skull base reconstruction – Temporary obturator for 2–3 months till complete contracture occurs. – Final maxillary prosthesis after 2–3 months.	**Follow-up** • Regular follow-up as usual for all head-neck malignancies. • Follow up every 2–3 months for the first 2 years, every 4–6 months for the next 3 years and annually thereafter. • Surveillance is to be done using an endoscope. • Baseline post-treatment imaging (MRI preferred) to be done 3 months after completion of treatment. • Follow-up imaging with MRI is recommended annually for at least 2 years, thereafter when symptomatic. • In case of a cavity closed by a free flap, surveillance with MRI is recommended. • Dental evaluation, speech and swallowing evaluation, ophthalmological evaluation, and thyroid function on follow-up.	

9.7 Salivary Gland Tumors

Treatment recommendations are based on retrospective reviews of clinical experience, and there are almost no data from randomized trials to guide treatment decisions. Surgery is the mainstay of treatment for resectable, non-metastatic salivary gland tumors. The surgical approach and the extent of resection depend upon the location and extent of the tumor (see Table 15). Facial nerve monitoring is a useful aid to identify the nerve during surgery. However, practice varies widely across the world and it is yet to be considered as a standard of care, there is a significant reduction in immediate post-operative paralysis but not in permanent facial nerve impairment. Also, the benefit of using the nerve monitor is greater in recurrent cases. Neck dissection is done in all cases with cN+ Neck and in cN0 neck with certain high-risk features (grade, extraparenchymal extension, high-risk histologies, and size).

Early-stage, low-grade malignancies including low-grade mucoepidermoid carcinomas, acinic cell carcinomas, and

Table 15 Management algorithm for salivary gland tumors

Staging workup	**Other workup**
• History and physical examination • FNAC: Safe and effective with high sensitivity and specificity • Core biopsy: May be considered where an initial FNA is either inconclusive or equivocal • USG: Simple and inexpensive, however, not comprehensive enough for assessing the deep lobe of the parotid or parapharyngeal space • CT scan: Where bone destruction is suspected at the skull base or o suspected involvement of the mandible and to assess neck nodes • MRI: Better soft tissue delineation, delineation of the interface between tumor and normal salivary gland, better imaging of the parapharyngeal space, perineural spread, and facial nerve status	• Neurological testing for facial nerve • Dental prophylaxis
Treatment algorithm	
Parotid gland	**Submandibular gland**
• Benign parotid tumors – Superficial parotidectomy or partial parotidectomy for benign tumors of the superficial lobe – Total conservative (nerve-sparing parotidectomy): For larger tumors and tumors involving deep lobe • Malignant tumors – Superficial parotidectomy for early (T1–T2) low-grade malignant tumors of superficial lobe – Total parotidectomy in high-grade malignant tumors, T3–4 tumors, Tumours with extraparenchymal spread, and malignant tumors of the deep lobe – Facial nerve sacrifice is done if there is preoperative or intraoperative evidence of involvement. Clear margins at both ends need to be ensured. Mastoidectomy and exploration of the intratemporal part of the facial nerve may be required to achieve a negative proximal stump. This may be followed by facial nerve reconstruction using a nerve graft. – If there is an extension beyond the parotid, the surgery may extend to involve resection of the skin, mandible, mastoid, temporal bone, or infratemporal fossa followed by appropriate reconstruction.	• En bloc resection of the gland with SOHD and any involved structure in the submandibular triangle • Resection may extend to the floor of the mouth and mandible • In adenoid cystic carcinoma: Excision of the hypoglossal and lingual nerves may be needed if intraoperative thickening is noticed
• Management of neck: Ipsilateral neck dissection (MND) is the standard for a cN+ neck. Selective neck dissection (SOHD) may be warranted for cN0 neck in T3, T4 tumors, high-grade tumors, extra-parenchymal spread, and certain histological types (undifferentiated carcinoma, squamous cell carcinoma, adenocarcinoma NOS, carcinoma ex-pleomorphic adenoma, and salivary duct carcinoma) • Unresectable disease: Definitive RT, if poor PS palliative RT • Metastatic disease: Palliative radiotherapy or systemic therapy may be considered for symptom control. Metastasectomy may play a role in patients with limited metastases, controlled primary, and non-aggressive histologies in good performance status	
Adjuvant radiotherapy: – No level I or level II evidence to support the use of adjuvant RT. A large number of prospective and retrospective studies are the guidelines for the use of PORT – Indications: T3/T4 cancers, close or positive margins, lymph node metastasis, high or intermediate grade tumors, high-risk histology, adenoid cystic carcinoma, adenocarcinoma, salivary duct carcinoma, high-grade MEC, and carcinoma ex-pleomorphic adenoma, perineural invasion and recurrent tumors. Adjuvant chemoradiation: Clear role not defined, explored in patients with T3–4, or N1–3 disease, intermediate or high-grade tumors, and positive or close ($\leq$1 mm) microscopic margins of resection.	
Follow-up • Regular follow-up as usual for all head-neck malignancies • Follow up every 3–4 months for the first 2 years, every 4–6 months for the next 3 years and annually thereafter • Follow-up should include a thorough clinical examination • Routine CT/MRI scans are not recommended: Imaging for suspected locoregional recurrence	

low-grade adenocarcinomas are well controlled with complete surgical resection, with control reaching 85 percent at 10 years. Adjuvant RT generally is not indicated if adequate margins are obtained. There is no level I or level II evidence to support the use of adjuvant RT. A large number of prospective and retrospective studies are the guidelines for the use of PORT.

Indications are:

- T3/T4 cancers
- Close or positive margins
- Lymph node metastasis
- High- or intermediate-grade tumors
- High-risk histology (adenoid cystic carcinoma, adenocarcinoma, salivary duct carcinoma, high-grade MEC, carcinoma ex-pleomorphic adenoma, perineural invasion, and recurrent tumors)

The optimal adjuvant radiation dose for a malignant salivary gland tumor depends upon the fractionation scheme utilized, but most use doses of 60–66 Gy. The radiation treatment volume encompasses the original tumor bed and regional lymph nodes only if involved or thought to be at high risk. For adenoid cystic carcinoma, neural pathways to the skull base are also included. Conformal RT techniques are preferred.

The role of definitive radical RT is restricted to unresectable tumors. This form of treatment is usually of palliative intent. Fast neutron beam therapy has been shown to be beneficial. However, its use is limited by the extremely scarce availability of fast neutron RT units.

The role of chemotherapy in salivary gland tumors is limited to upfront or recurrent locally advanced inoperable tumors (where the intent is usually palliation rather than cure) and as adjuvant treatment along with radiation ins selected cases. There has been a lot of research with respect to biomarkers and targeted agents designed against the same. This has generated vast amounts of literature that need to be critically analyzed and interpreted before being incorporated into clinical practice.

Concurrent chemoradiation in the adjuvant setting has been offered for the following indications: T3–4, or N1–3 disease, intermediate or high-grade tumors, and positive or close (≤1 mm) margins of resection. In a large retrospective analysis [62] using records from the National Cancer Database (NCDB), patients undergoing chemoradiation were seen to have poorer outcomes than those receiving adjuvant radiation alone. It is to be noted that there was significant heterogeneity between the two groups with reference to adverse prognosticators like histology, grade, and TNM stage, rendering the evidence unreliable. This controversy surrounding the role of adjuvant chemoradiation remains unanswered for now.

Systemic therapy alone is considered in locally advanced incurable tumors or recurrent/progressive advanced tumors for symptom control and palliation. Multiple regimens have been used in salivary gland tumors. In general, response rates are higher in poly chemotherapy regimens as opposed to the single-agent regimen. Selection of chemotherapy should take into consideration the histology and ability to tolerate chemotherapy Staging can be found in AJCC Cancer Staging Manual, Eighth Edition, Page no. 99–100, Chapter no. 08, Major Salivary Glands, Table: Definition of TNM and AJCC prognostic stage groups which can be accessed at https://emedicine.medscape.com/article/2047666-overview and management in Table 15.

10 Stage-Wise Prognosis with Current RX

10.1 Head and Neck Cancer (Non-nasopharyngeal and HPV −ve Head and Neck Cancer)

Stage	5-Year relative survival (95% CI)
I	69.5–73.5%
II	55.5–60.4%
III	41.8–47.3%
IV	33.6–40.3%

10.2 Nasopharynx

Stage	5-Year relative survival [63]
I	98%
II	92%
III	83%
IV	71%

10.3 Oropharynx (HPV+)

Stage	5-Year relative survival (95% CI) [64]
I	88 (65–91%)
II	81 (77–86%)
III	65 (58–72%)

11 Management of Recurrent Disease Including Specific Palliative Measures

11.1 Nasopharynx

Locoregional failure after initial treatment is seen in approximately 10% of patients. Early detection of loco-regional failure can provide a better chance of salvage. Therefore, regular follow-up of patients is recommended.

PET-CT is superior to CT/MRI in differentiating tumor recurrence from radiation fibrosis. Plasma EBV DNA levels are another useful biomarker for early detection of recurrence, plasma EBV DNA levels may be elevated up to 6 months prior to a clinical recurrence. Recurrent NPC could be treated either by surgical salvage or re-irradiation.

11.1.1 Role of Surgery

Surgery provides good local control with 5-year survival rates ranging between 30% and 50% in recurrent/persistent NPC, especially with early lesions. Surgery also plays a significant role in the treatment of radio-resistant histologies. Surgery is usually performed through open approaches (lateral approach, trans-palatal, mandibular swing, and maxillary approaches) which require translocation of the maxillofacial skeleton or the transposition of critical neurovascular structures. These approaches are associated with significant morbidity especially due to the associated risk of cranial nerve injuries. This has led to the evolution of minimal access, minimally invasive procedures.

Endoscopic endonasal nasopharyngectomy is a feasible minimal access technique indicated for the resection of select recurrent and radio-resistant nasopharyngeal malignancies. It bestows the advantages of lack of external incisions or scars, decreased trauma to adjacent soft tissues and bone, reduced risk of neurological damage, and superior postoperative quality of life.

Chen et al. carried out an endoscopic nasopharyngectomy in 37 recurrent NPC, almost all of them with rT1–T2 tumors. No severe complications or deaths resulting from the operation were observed. The 2-year overall survival rate, local relapse-free survival rate, and progression-free survival rate were 84%, 86%, and 83%, respectively. Robotic-assisted endoscopic nasopharyngeal resection may also play a very important role in these difficult situations.

11.1.2 Role of Re-irradiation

Endocavitary brachytherapy, interstitial brachytherapy, stereotactic radiosurgery, intensity-modulated radiotherapy, and particle beam radiotherapy are various modalities used for re-irradiation in recurrent NPC. A judicious case selection taking into account previous radiation dose, previous radiation volume, interval after previous RT, and current tumor bulk is essential for the success of Re-Irradiation. Promising results are seen, with local control and survival equivalent to nasopharyngectomy in rT1–rT3 lesions. IMRT has emerged as a promising technique of re-irradiation with low complication rates. The complications commonly reported after re-irradiation for NPC include massive epistaxis, nasopharyngeal necrosis, cranial nerve palsies, temporal lobe necrosis, and osteoradionecrosis of the skull base.

11.2 Oral Cavity

Management of recurrences requires a thorough clinical examination and restaging evaluation with PET-CT to rule out metastatic disease. Patients with good performance status, resectable small-volume recurrences, and long disease-free intervals are most likely to benefit from salvage treatment. Salvage surgery is the best option if feasible and should be followed up by Re-irradiation if indicated and possible as it is shown to improve DFS [65]. Unresectable recurrences may be considered for re-irradiation; however, outcomes are not favorable.

11.3 Oropharynx

PET-CT should be performed in recurrent cases to rule out metastatic disease. For resectable recurrences, salvage surgery should be performed followed by re-irradiation if feasible. Unresectable recurrences should be treated with re-irradiation if possible, if surgery or re-irradiation is not possible systemic therapy may be considered.

11.4 Larynx and Hypopharynx

For resectable recurrences after previous surgery or radiotherapy, salvage surgery should be performed followed by chemo-radiation or re-irradiation (depending on if previ-

ously irradiated or not). Unresectable recurrences are treated with chemo-radiation (if not previously irradiated) or re-irradiation if possible, if surgery or Re-irradiation is not possible systemic therapy may be considered. If in poor general condition then Palliative radiation/chemotherapy or BSC as tolerated to achieve the best symptomatic control.

11.5 Nasal Cavity and Paranasal Sinuses

Resectable recurrences: Salvage surgery followed by re-irradiation if feasible.

Unresectable recurrences: Chemo-radiation (if not previously irradiated) or re-irradiation if possible, if surgery or Re-irradiation is not possible systemic therapy may be considered.

11.6 Salivary Gland Tumors

Resectable recurrences: Surgery is preferred, surgery in these situations has a high risk for facial nerve damage.

Unresectable recurrences: Irradiation should be considered.

If neither surgery nor irradiation is feasible (e.g., previously irradiated), systemic chemotherapy may be considered.

Figure 2 presents a management algorithm for recurrent HNC.

VEGF	Vascular endothelial growth factor
VEGFR	VEGF receptor
WHO	World Health Organization

1 Introduction

Thyroid cancers are the most common endocrine malignancy that is either follicular cell-derived (FCDC), arising from the parafollicular C cells of neuroendocrine origin which are the medullary thyroid cancers (MTC) or anaplastic. FCDC account for 90% of all thyroid malignancies and are of four types—papillary (most common), follicular, Hurthle cell and poorly differentiated thyroid cancers. These vary in biological aggressiveness from well-differentiated to the poorly differentiated cancers. World Health Organization (WHO) classifies Hurthle cell carcinoma a separate entity and not a variant of follicular carcinoma due to their peculiar behavior [1]. Papillary thyroid cancer has several variants namely papillary microcarcinoma, encapsulated, the follicular and cribriform morular variant which have an excellent prognosis; high-risk variants like diffuse sclerosing, tall cell, columnar cell, hobnail, oncocytic and solid/trabecular variant and others like spindle cell, clear cell and Warthin-like which are extremely rare and their clinical behavior is poorly understood [2]. Majority of these cancers are sporadic with <5% being hereditary in origin.

2 Incidence and Epidemiology

Globocan data report the age-standardized rate (ASR) of 6.7 per 100,000 people with 567,233 being diagnosed worldwide annually. The incidence is lower in India with ASR of 1.4 per 100,000 people and 18,688 new cases being reported every year [3]. Vecchia et al. observing the incidence and mortality trends over four decades noted a significant rise in the incidence of thyroid tumors particularly papillary thyroid cancer (PTC) with a stable decrease in mortality during this time period. The mortality has declined with an annual percentage change of −2/−3% in men and −2/−5% in women in most major countries of the world. This incongruity between the incidence and mortality has been attributed to overdiagnosis which is secondary to the increased use of

imaging [4]. These tumors are usually small and are diagnosed in the preclinical stage which would have stayed unnoticed in all probability in the lifespan of the individual [5, 6]. Others have argued that in addition to this apparent increase due to over diagnosis, there is a true increase in incidence. This stems from the fact that the rise in incidence is observed not only for small tumors but also for tumor with high volume and across all stages. Lim et al. observed the trends of thyroid cancer mortality and incidence from the Surveillance, Epidemiology and End Results-9 (SEER-9) data. There was an average 3.6% increase in the incidence of thyroid cancers annually which was primarily related to PTC. The increase per year was 4.6%, 4.3% and 2.4% for localized, regional and distant disease respectively for PTC [7]. Also, the increase is more in females compared to males and in specific birth cohorts. The increase has been attributed to environmental carcinogens and medical radiation [8].

3 Differentiated Thyroid Cancers

3.1 Clinical Presentation

Thyroid cancers present as a solitary nodule in the majority of cases while the remaining present as multiple nodules or diffuse enlargement of the gland. Well-differentiated thyroid cancers affect females about 3 to 4 times more than males. PTC presents with small thyroid nodules less than 2 cm in size and is early staged in more than 80% in the western world, as mentioned earlier attributed to increased screening/imaging [8]. These tumors can be multifocal in as high as 60% in papillary microcarcinoma [9]. The prevalence of regional and distant metastasis at the time of presentation is about 20% and 2%, respectively. However, the true initial prevalence based on the histopathology and I-131 therapeutic whole-body scans is higher with 30% regional and 10% distant metastasis [10]. Papillary thyroid cancer is characterized by a lymphatic spread with a high incidence of nodal metastasis whereas follicular carcinoma has the predilection for hematogenous spread. About 10% to 15% of follicular carcinoma can have distant metastasis at the time of presentation. The incidence of distant metastasis rises to as high as 34% during the course of the disease, particularly in Hurthle cell carcinomas [11]. Distant metastasis is synchronous in 40% to 55% with the most common site being lung (43–49%) followed by bone (24–33%) [12–14]. Metachronous distant metastasis (occurring >12 months after the initial diagnosis) occurs in 45% and have poorer survival compared to synchronous metastasis [14]. The extrathyroidal extension (ETE) is seen in 10% to 32% of cases and the decreasing order of occurrence involves strap muscles, recurrent laryngeal nerve (RLN) and trachea [11, 15]. Thyroid cancer is the only site in the body where age is an important prognostic factor [16]. The tumor size and regional metastasis increase are seen at extreme ages. The features of biological aggressiveness including capsular invasion, extrathyroidal extension and neural or vascular invasion are more frequent in the younger population [17]. Despite these features of pediatric DTC, the survival outcomes of the children and young adult are the same [18]. Locally advanced thyroid cancers may present with the symptoms of hoarseness and aspiration with RLN involvement and resultant vocal cord fixation. Stridor or hemoptysis indicates laryngotracheal invasion. Gross ETE may cause infiltration of the upper aerodigestive tract and deviation of the larynx and trachea.

3.2 Evaluation and Work-Up

Thyroid function test (T3/T4/thyroid-stimulating hormone [TSH]) is the first test ordered in the workup of any thyroid nodule. Thyroid cancer with hyperthyroidism is an exception rather than a rule and mandates a radionuclide scan (iodine-123 or technetium 99mTc pertechnetate) to assess for the presence of hyperfunctioning nodule which almost always denotes benignity. However, a nonfunctioning cold nodule should be investigated further as the risk of malignancy in these nodules is high ranging from 5% to 15% [19]. Thyroid cancer usually arises in the background of a euthyroid status sometimes with a raised TSH. Gross hypothyroidism is usually a medical condition.

Given the high incidence of thyroid nodules in the general population and the presence of occult microcarcinoma, a diagnostic workup is recommended only for nodules >1 cm to avoid overtreatment of cancers that are probably incidental and would never manifest in the lifetime of a patient. In the case of multinodular goiters (MNG), size of 2 cm is suggested as the cut-off for further investigation by the American Thyroid Association (ATA) [20]. This is important as MNGs are common in our part of the world. High-risk nodules viz. those diagnosed incidentally on PET scans for other causes, nodules in children, a family history of thyroid cancer and those with a prior history of exposure to radiotherapy in childhood are investigated irrespective of nodule size given the high likelihood of harboring a malignancy.

DTC is associated with reliable tumor markers namely thyroglobulin. However, its role is limited as a diagnostic or baseline screening tool. Thyroglobulin has low sensitivity and specificity with the thyroid gland in-situ as it is raised in other conditions as well (thyroiditis, benign goiters, etc.). The main role of these markers is in the follow-up of patients for early detection of disease recurrence.

Locally advanced presentation with the invasion of surrounding structures is seen in 13% to 15% of thyroid cancers which most commonly involved straps followed by RLN [21]. It must be kept in mind that only a third of these patients

Table 1 Bethesda system for reporting thyroid cytopathology: risk of malignancy

Bethesda category	Risk of malignancy (%) [98]	Re-estimated risk of malignancy[a] (%) [99]	Suggested management
Nondiagnostic or unsatisfactory (Bethesda I)	1–4	5–10	Repeat FNAC under USG guidance
Benign (Bethesda II)	0–3	0–3	Observe if surgery not warranted for cosmesis, size/pressure
Atypia of undetermined significance or follicular lesion of undetermined significance (Bethesda III)	5–15	6–18	Observe[b]/diagnostic lobectomy/ molecular markers
Follicular neoplasm or suspicious for a follicular neoplasm (Bethesda IV)	15–30	10–40	Observe[b]/diagnostic lobectomy/ molecular marker
Suspicious for malignancy (Bethesda V)	60–75	45–60	Diagnostic lobectomy
Malignant (Bethesda VI)	97–99	94–96	Therapeutic hemi/total thyroidectomy

[a] Risk estimation considering NIFTP as nonmalignant

[b] If nodule size is small, no high-risk factor on history or clinical examination, no high-risk radiological features

present with a change in voice [11]. Fiber optic laryngoscopy should be performed in every case and function of the cord should be documented both to alert the clinician of possible nerve involvement as well as for medicolegal issues. Laryngotracheal framework infiltration should be confirmed on endoscopy if suspected following imaging.

Ultrasonography (USG) is the initial imaging of choice given its multiplanar capability, easy availability, affordability and the lack of radiation exposure. It helps to assess the echogenicity, size, location, tumor and gland interface and characterizes the tumor as cystic or solid. High-risk features suggestive of malignancy are a solid hypoechoic nodule, presence of microcalcification, micro lobulations or irregular margins and a nodule that is taller than wide. These five high-risk features form the basis of the TIRADS (Thyroid Imaging Reporting and Data Systems) which is a diagnostic classification used to estimate the risk of malignancy (ROM) in the thyroid nodules [22]. The biggest disadvantage of sonography is that it is highly operator dependent. Besides, the sensitivity to detect nodal metastasis in the central compartment is low. Nodes in the retro/parapharyngeal region and mediastinum are also not visualized on sonography. Addition of cross-sectional imaging improves the sensitivity in detecting these nodal metastases both in the central and lateral compartment.

Cross-sectional imaging is needed in cases with locally advanced cancer to accurately assess the extent of disease. Contrast-enhanced computed tomography (CECT) is the imaging modality of choice when laryngotracheal framework involvement is suspected. Magnetic resonance imaging (MRI) and endoscopic ultrasound have higher sensitivity in evaluating esophageal involvement.

Fine-needle aspiration cytology (FNAC) is performed to establish the diagnosis. It is preferably performed under the US guidance particularly when the tumor is small or posteriorly located. The ideal cytology smear targets at obtaining at least 5–6 follicular cell groups with each group having 10–15 cells preferably on single slide [23]. FNAC reporting is now standardized with various reporting systems described in the literature. The Bethesda system is most widely adopted and is used to estimate the ROM classified under six categories. The recent recognition of well-differentiated tumors of uncertain malignant potential/noninvasive follicular thyroid neoplasm with papillary-like nuclear features has led to a recalibration of the Bethesda system of classification (Table 1). While the accuracy of FNAC for diagnosing PTC is high it has limited utility in establishing the diagnosis of follicular and Hurthle carcinoma given that capsular and vascular invasion, the essential prerequisites of malignancy cannot be demonstrated by FNAC. This, therefore, results in about 25% of the FNAC's being reported as indeterminate on the Bethesda system. While guidelines recommend considering molecular profiling in these cases it has not translated into the incorporation in routine practice. The main reasons are high costs, relative lack of availability and results that have not been corroborated in real-world practice. Moreover, the majority of these nodules turn out to be benign or are indolent cancers on final histopathology with no real detriment to survival had the patient been on active surveillance. A pragmatic approach, therefore, would be to use these tests when the clinicoradiological findings reveal high-risk features which would prompt the clinician to a diagnostic lobectomy. These tests can be useful in this cohort to help avoid surgery. However, it should be kept in mind that the negative predictive value (NPV) of these tests in such a scenario may be lower than what has been reported in the literature [24, 25].

3.3 Principles of Management

Surgery is the mainstay of treatment for thyroid cancers. Close to 90% of thyroid cancers are differentiated and have an excellent prognosis and low mortality in the majority. Therefore, the aim of the management of these cancers is complete surgical clearance of disease while avoiding treatment-related morbidity. The RLN damage can occur in

0.5% to 3% of patients, while hypoparathyroidism (temporary/permanent) has been reported in as high as 20% of patients even in the most experienced hands [26]. Surgery must therefore be adequate with the gross clearance of disease. Overzealous clearance does not offer survival benefit but increases the risk of hypoparathyroidism and RLN injury, on the other hand, inadequate surgery increases the risk of recurrence and resurgery is associated with higher morbidity. Given the unpredictable and relatively high rates of complications following surgery and the fact that thyroid occult papillary microcarcinomas are common in a significant proportion of the general population, there is a school of thought that advocates observation in select cases with microcarcinomas. The ideal patient for this approach must have a purely intraparenchymal tumor, preferably not posteriorly located (where there is a risk of RLN fixation) and without nodal metastasis. Surgery is recommended only in case of disease progression, i.e., increase in nodule size or the appearance of metastatic nodes. This approach of surveillance was first shown to be safe from large series from Japan and subsequently by others as well [27, 28].

3.3.1 Surgical Management of Differentiated Thyroid Cancers

Primary Tumor

To optimize outcomes a judicious decision needs to be made regarding the extent of surgery weighing benefits against potential morbidity. Morbidity of surgery is influenced by the volume and expertise of the surgeon [29]. Bilateral procedures for logical reasons place patients at a higher risk of complications than unilateral procedures [26]. Besides, differentiated thyroid cancers are indolent with an excellent prognosis in the majority of patients. This forms the premise of a debate to the optimum surgical procedure of hemi versus total thyroidectomy in DTC. Proponents of hemithyroidectomy suggest that it is associated with lower morbidity, recurrence in the contralateral lobe can be salvaged if needed and most importantly that there is no proven determent in survival with this approach. Advocates of total thyroidectomy argue that the procedure reduces the risk of recurrence and is not associated with a significantly higher rate of complications in experienced hands. Also, total thyroidectomy facilitates follow-up in that it increases the reliability of thyroglobulin as tumor marker postoperatively and helps in early disease detection should the recurrence occur.

Bilimoria et al. showed that the extent of surgery affects recurrence and survival in tumors >1 cm recommending total thyroidectomy in these patients from a large national cancer database (NCDB) of 52,173 patients [30]. Hay et al. studied the temporal trends in patients classified as low risk according to MACIS (distant metastasis, patient age, completeness of resection, local invasion and tumor size). About 70% of cases underwent lobectomy between 1940 and 1949, 22% between 1950 and 1959 and thereafter between 1960 and 1999, 91% of patients underwent total thyroidectomy. The results showed cause-specific mortality and tumor recurrence was significantly higher between 1940 and 1949 compared to between 1950 and 1999 [31]. Mazzaferri et al. in a study of 1355 patients reported that for tumors >1.5 cm near-total thyroidectomy followed by RAI ablation decreased tumor recurrence and mortality [32]. Meta-analysis of 2939 patients showed that for tumor size ≤1 cm thyroid lobectomy was associated with high recurrence rates [33]. Another meta-analysis analyzed the risk factors influencing recurrence in PTC and showed that tumor size >2 cm and subtotal thyroidectomy were significant in addition to other factors, including gender, ETE, lateral lymph node and distant metastases and receipt of radioactive iodine [34]. Recently published study of 5266 patients with tumors 1–4 cm showed that lobectomy is associated with higher recurrence rates and lower disease-free survival [35]. All these studies are in favor of total thyroidectomy in patients with tumor size >1–2 cm. There are studies however that are at variance with the above and favor hemithyroidectomy as an oncologically safe procedure for tumors up to 4 cm. Adam et al. in an updated analysis of NCDB of 61,775 patients showed that after adjustments for demographics, clinical factors and pathological factors; the overall survival (OS) of lobectomy and total thyroidectomy was similar for tumors between 1 and 4 cm [36]. Similarly, reports from the SEER database have shown that extent of surgery does not impact survival in these patients [37–39]. Nixon et al. similarly reporting on 889 patients with T1T2N0 tumors (<4 cm) showed that the extent of surgery does not impact OS, local or regional recurrence [40]. Recently published propensity scores matched-pair analysis comparing the outcomes of lobectomy versus total thyroidectomy in 2345 patients reported no DFS benefit with total thyroidectomy and suggested that the extent of surgery was not an independent factor predicting recurrence for tumor size between 1 and 4 cm [41].

This state of clinical equipoise between hemithyroidectomy and total thyroidectomy for tumors less than <4 cm prevails because of the lack of randomized-controlled trial (RCT) and conflicting results across many studies. To confound factors, making interpretation difficult all these studies are mainly retrospective in nature with heterogeneous patient populations and study outcomes.

To put the current literature in proper perspective there is no debate that in patients with a tumor less than 1 cm with no other high-risk feature (nodal metastasis, distant metastasis, prior history of radiation exposure or hereditary cancers) hemithyroidectomy is an adequate procedure while all tumors >4 cm should undergo total thyroidectomy. For tumors between size 1 and 4 cm either a total or hemithyroidectomy is considered adequate in the absence of other high-risk features. Total thyroidectomy is also preferred to facilitate postoperative radio-iodine treatment if deemed necessary by the treating clinicians based on tumor and patient characteristics and help follow-up. Patients and the family must be taken into confidence and counseled with regards to the pros and cons of either procedure and the decision taken in conjunction.

Unlike in other cancers, the prognostic detriment of lymph node metastasis in differentiated thyroid cancer is uncertain and usually does not impact outcomes in the majority. The first echelon of nodal spread in the majority of thyroid cancers is the central compartment, an area that extends from the hyoid superiorly to the innominate artery inferiorly and is bounded by the carotids on either side laterally. Given the risk to the RLN/parathyroids, routine prophylactic central compartment clearance is not recommended in early DTC with no high-risk features due to the possible morbidity associated with the procedure. Central compartment clearance is however recommended when there is nodal involvement, in locally advanced T3/T4 tumors and in the presence of lateral compartment metastasis (80% will have metastatic nodes in the central compartment) [20]. Lateral neck dissection is indicated only in the presence of metastasis and surgery should entail clearing level II–V. There is no role of "berry picking" given that this procedure is associated with a high rate of nodal recurrences.

3.3.2 Radioactive Iodine (RAI) Treatment

The indications and need for radioiodine have undergone a paradigm shift in the recent past with lesser patients being treated with RAI. ATA guidelines stratify thyroid cancers into low, intermediate and high risk (Table 2). High-risk cancers warrant RAI treatment while it should be considered for those with intermediate-risk. Schlumberger et al. conducted phase III 2 × 2 factorial RCT (ESTIMABL1) to compare the thyrotropin stimulation methods (thyroxine withdrawal versus recombinant human thyrotropin) and to determine the ideal dose of RAI (1.1 GBq versus 3.7 GBq) in low-risk thyroid cancers. The authors concluded that recombinant thyrotropin and low dose (1.1 GBq) were adequate for the management of low-risk cancers [42]. The long-term follow-up of the trial at the median follow-up of 5.4 years reconfirmed the findings and the results showed that the disease recurrence was not related to the ablation strategy [43]. Mallick et al. in a multicentric noninferiority trial (HiLo) similarly comparing the dose of RAI (30 mCi versus 100 mCi) and influence of using either recombinant human thyrotropin (thyrotropin alfa) or thyroid hormone withdrawal for T1–T3 DTC concluded that low dose and thyrotropin alfa were equally effective and were associated with lower rates of adverse events [44]. The long-term results of the trial confirmed the finding and reported a similar recurrence rate in the two arms [45]. Based on a recently published randomized controlled trial (ESTIMABL2), RAI is not routinely advocated for low-risk cancers [46]. The trial randomized 730 low-risk thyroid cancers and showed that follow-up without iodine ablation was non-inferior to iodine ablation strategy in terms of functional, structural, and biologic events at 3 years. There is another ongoing phase III trials comparing the outcomes of low dose RAI versus observation in low-risk thyroid cancers (IoN:NCT01398085) [47].

3.3.3 Radiation Management

The role of external beam radiotherapy in DTC is contentious and there is a paucity of published literature on this topic. The only multicentric prospective trial designed to establish the clinical benefit of external beam radiotherapy (EBRT) in locally invasive thyroid DTC was converted to a prospective cohort study due to patients' refusal to consent for randomization. EBRT showed a weak statistically not significant benefit in this trial and the authors recommended discontinuation of routine adjuvant EBRT in DTC [48]. The Endocrine Surgery Committee of the American Head and Neck Society suggest to consider EBRT in patients with gross residual or unresectable locoregional disease, and in older patients with a high probability microscopic residual disease which may not respond to RAI [49].

Jacomina et al. in a recent meta-analysis attempted to establish the indications of EBRT in DTC. The meta-analysis including 9 studies with 2981 patients compared oncologic

Table 2 Risk stratification of thyroid nodules (adapted from ATA guidelines): risk of disease recurrence

Risk category	Features	Recommendation for RAI	Recommended TSH levels (mU/L)
Low	Intrathyroidal PTC (2–4 cm) Minimally invasive FTC ≤5 Lymph nodes with micro metastasis (<0.2 cm)	Observe	0.5–2
Intermediate	Aggressive histology Lesion >4 cm in size with minimal ETE >5 Nodes (0.2–3 cm) Vascular invasion	Consider	0.1–0.5
High	Gross ETE, extensive vascular invasion in FTC, distant metastasis, lymph node >3 cm	Recommend	<0.1

PTC papillary thyroid cancer, *FTC* follicular thyroid cancer, *ETE* extrathyroidal extension outcomes and toxicity with and without RT. Results showed that the addition of adjuvant RT improves locoregional recurrence-free survival but it did not add any benefit to OS or distant metastasis-free survival. This advantage was observed in patients with advanced age, a locoregionally advanced disease with structural invasion and gross or microscopic residual disease [50]. Another systematic review of 16 studies including 5114 patients suggested benefit of EBRT in locoregional control in patients with advanced age >45 years at high-risk of locoregional recurrence [51]. However, there is a need for larger more robust data to establish the true role of adjuvant radiotherapy in DTC.

3.3.4 Thyroxine Replacement Post Thyroidectomy

The DTCs are TSH-dependent, and hence, patients should be administered supraphysiological doses of thyroxine as a replacement. A meta-analysis of 4174 patients showed that thyroid hormone suppression therapy after initial therapy decreased the risk of disease progression/recurrence and death [52]. However, high doses of thyroxine are known to be associated with diminished cardiac reserve, atrial fibrillation and premature osteoporosis [53, 54]. Therefore, the dose should be adjusted judiciously weighing the benefit against the morbidity. The suppression therapy does not offer any disease-free survival benefit in low-risk cancer patients [55]. The degree of suppression should be guided by the aggressiveness and risk of recurrence should be taken into consideration. The high-risk or recurrent tumor should undergo more aggressive thyrotropin suppression whereas it has to be less aggressive in low-risk tumors. Intermediate-risk tumors who are at high risk of adverse effects should undergo evaluation during the follow-up and dose titration [56]. Recommended TSH levels are 0.5–2.0 mU/L for low-risk, 0.1–0.5 mU/L for intermediate and <0.1 mU/L for high-risk patients [20]. The risk stratification of patients is dynamic and changes with time, e.g., a high-risk patient who stays disease-free for years is then treated as intermediate and subsequently low-risk. Similarly, a low-risk patient with recurrence is considered to be at intermediate/high-risk and thyroxine dose should be appropriately titrated.

3.4 Stage-Wise Prognosis with Current Treatment

Age is a strong prognosticator for DTC and has been considered in the AJCC cancer stage grouping. Age cut off of 45 years was considered as distinguishing between low and high-risk cancers. Recently Nixon et al. performed recursive partitioning analysis on 1807 patients and reported that age cut off of 56 and 54 years for patients without and with distant metastasis respectively years is an important predictor of disease-specific survival [57]. Following this study, the age cut off has been changed from 45 to 55 years in recent 8th edition American Joint Committee on Cancer (AJCC) staging. AJCC classifies disease <55 years as stage I in the absence of DM and stage II with DM irrespective of T and N stage. For the patients' age ≥55 years tumor size, extrathyroidal extension and distant metastasis are the independent prognostic factors. These factors are therefore taken into consideration for stage grouping. The 5- to 10-year OS for stage I and II cancers are between 97% and 100%; 88% and 95% for stage III and 50% and 75% for stage IV [16].

3.5 Management of Recurrent Disease Including Specific Palliative Measures

Management of advanced or metastatic cancer is a challenge due to the limited efficacy of radiotherapy and conventional chemotherapy. Hence, whenever possible surgery or RAI must be considered as the first choice. Chemotherapy is only considered in recurrent metastatic cancers that are radioiodine refractory or when surgical salvage is not possible. Conventional chemotherapy has a limited role in thyroid cancers. Fortunately, the genetic landscape of DTC demonstrates numerous genetic alterations rendering them suitable for targeted therapy. The common alterations are the BRAF point mutation, RET-PTC translocation and RAS point mutation. Also, vascular endothelial growth factor (VEGF) and VEGF receptor (VEGFR) are associated with aggressiveness and metastasis and a potential target for treatment. Tyrosine kinase inhibitors (TKI) targeting these pathways have been widely researched and have demonstrated benefit. Both Sorafenib and Lenvatinib are molecules that have been researched in randomized trials in radioiodine refractory DTC. Sorafenib is an oral tyrosine kinase inhibitor targeting various VEFGRs 1–3, BRAF, RET/PTC and platelet-derived growth factor receptor (PDGFR) β. Lenvatinib is an oral multikinase inhibitor of VEGFRs 1–3, fibroblast growth factor receptors (FGFRs) 1–4, PDGFR α, RET and KIT signaling pathway. In Phase III randomized-controlled trial (DECISION) in radioiodine refractory locally advanced and metastatic DTC Sorafenib showed significant median progression-free survival (PFS) improvement over the placebo (10.8 months versus 5.8 months respectively). This benefit was seen across all prespecified clinical and biomarker subgroups irrespective of the mutation status [58]. Similarly, Lenvatinib, when compared to a placebo in phase III RCT (SELECT) in iodine refractory progressive thyroid cancer, demonstrated a significantly better median PFS (18.3 months versus 3.6 months, respectively) [59]. Interestingly this improvement in PFS was longer than that observed with sorafenib. Also, the median PFS in the placebo group was significantly lower than the expected 8 months indicating that patients enrolled in this trial may have had a more aggressive disease.

Targeted therapy should be used judiciously as they are often associated with significant toxicity impacting on the patients' quality of life (QOL). The mere presence of asymptomatic disease does not warrant the initiation of treatment. Documented progressive locoregional or distant metastatic disease and symptomatic patients are indications for systemic therapy. Stereotactic radiosurgery is an alternative for symptomatic progressive disease when suitable in metastatic DTC which does not respond to RAI therapy.

4 Medullary Thyroid Cancers (MTC)

4.1 Clinical Presentation

Medullary thyroid cancers constitute about 5% of thyroid cancers and could be hereditary (25%) or sporadic (75%). Hereditary MTC occurs in younger patients, are mostly bilateral, multicentric and could be part of the multiple endocrine neoplasia (MEN) syndrome. MTC commonly presents as a solitary nodule in sporadic cases. The palpable MTCs are associated with regional metastasis in >75% of cases causing involvement of both central and lateral compartments [60]. Skip metastasis is seen in about 20% of cases where the central compartment is negative and metastasis directly occurs to the lateral compartment [61]. MTC may be associated with pheochromocytoma (50%), parathyroid neoplasm (20%) and Hirschsprung's disease or cutaneous lichen amyloidosis (MEN 2A) [62]. In MEN 2B, the MTC is associated with pheochromocytoma in 50% of the cases along with oral mucosal, conjunctival, intestinal ganglioneuromas and marfanoid habitus [63, 64]. Occasionally these patients may present with symptoms of flushing and diarrhea which is secondary to a very high level of calcitonin. In such cases workup for distant metastasis should be done to rule out pulmonary or liver metastasis [65].

4.2 Evaluation and Work-Up

In addition to routine evaluation mentioned under section DTC, these tumors need work-up for the hereditary MTCs. Familial medullary carcinoma expresses germline mutation in rearranged during transfection (RET) proto-oncogene which is located on 10q11.2. It is inherited as an autosomal dominant trait with partial penetrance. Given that the index case may be the first manifestation of a familial origin in 5% to 9% of patients with MEN2A which can be as high as 50% in cases with MEN 2B, when these mutations arise de novo, a RET protooncogene test is ordered in all cases even in the absence of strong family history [64, 66]. The RET mutation can be present on many different exons of the chromosome 10q which results in different ages of manifestation of the disease as well as different biological aggressiveness and these mutations are therefore classified into highest-risk, high-risk and moderate-risk. RET mutation positive patients need to be appropriately counseled and screened for pheochromocytoma before surgery. First-degree relatives should also undergo testing. Given its high penetrance, there is a role of prophylactic thyroidectomy among relatives who carry the mutation and have not manifested yet with the disease. The age of performing this procedure is determined by the type of mutation and aggressiveness of the disease.

Given the high incidence of nodal involvement, distant metastasis and the possible association with pheochromocytoma as part of a MEN syndrome, cross-sectional imaging is mandatory for every case of MTC. This could either be a CECT of the neck, thorax and abdomen (which should be triple phase CECT to identify liver metastases) or PET-CECT. The PET-CECT is now gaining acceptance as a one-step investigation for these cancers [67].

Calcitonin can help diagnose MTC but is not routinely performed in the workup of thyroid cancer as it is not cost-effective given the low incidence of these cancers. It is, however, helpful to corroborate the diagnosis in cases where FNAC is unable to subtype the tumor. Serum calcitonin is however essential as it acts as a marker to diagnose recurrence and tumor progression. Tumors with calcitonin doubling time less than 6 months have a poorer prognosis compared to the ones with more than 2 years [68]. Carcinoembryonic antigen (CEA) is another marker that is used in follow up of MTC and is a sign of dedifferentiation of the tumor. These markers help in prognostication as well as help guide initiation of TKIs in the treatment of recurrent tumors. Baseline calcitonin of more than 500 pg/mL acts as a surrogate for distant metastasis and should be corroborated with appropriate imaging.

4.3 Treatment Philosophy and Surgical Management

In contrast to DTCs, the minimum surgery recommended for MTC is total thyroidectomy given the multicentric nature of the disease. Central compartment dissection is recommended in all cases except when surgery is a prophylactic thyroidectomy based on RET oncogene mutation. Serum calcitonin levels can also help direct the extent of neck dissection. Machens et al. in a study of 300 patients found that serum calcitonin level thresholds of 20, 50, 200 and 500 pg/mL were associated with ipsilateral central and lateral neck, contralateral central neck, contralateral lateral neck and upper mediastinum lymph nodes, respectively [69]. The extent of neck dissection is best decided factoring the clinical neck node status, imaging and serum calcitonin. Regional metastasis in lateral compartment warrants neck dissection clearing level II through V on the ipsilateral side while the decision to address the contralateral neck if node-negative on imaging should be guided based on the serum calcitonin level.

4.4 Radiation Management

There exists a lack of trials addressing the benefit of EBRT in MTC. Recently published systematic review of 4 cohort studies, 22 retrospective and 1 prospective study looked at the role of EBRT in MTC both in the adjuvant setting as well as a primary modality in unresectable cases. It demonstrated there was no OS benefit with EBRT. However, in patients with nodal involvement, ETE or residual disease, radiotherapy reduced the risk of locoregional recurrence [70]. The ATA guidelines for MTC recommend considering EBRT in patients who are at high-risk airway obstruction and locoregional recurrence including extensive nodal disease, ETE or residual disease [64]. It is also recommended in cases with locoregional recurrence in whom surgery would be associated with high morbidity and risk. MTC is nonfollicular in origin, the thyrotropin levels in these tumors should be maintained within normal limits after the initial surgery. MTC has a prognosis between DTC and anaplastic cancer. The 5- and 10-year overall survival in MTC ranges between 60–100% and 55–100% respectively in the absence of metastasis [71].

4.5 Management of Recurrent Disease Including Specific Palliative Measures

Targeted therapy has shown to be of benefit in MTC in a palliative setting. Vandetanib, an inhibitor of RET kinase, VEGFR and epidermal growth factor receptor (EGFR) signaling, was compared to placebo in inoperable locally advanced or metastatic MTC in 331 patients (ZETA trial). The PFS was significantly prolonged in the Vandetanib arm along with better objective response rate, disease control rate and biochemical response. OS could not be commented on in this trial as the data was immature for meaningful analysis [72].

Cabozantinib, TKI of hepatocyte growth factor receptor (MET), VEGFR 2 and RET, was compared with placebo in 330 patients with radiographic progression of metastatic MTC in a phase III RCT. The median PFS was significantly better with Cabozantinib compared to placebo (11.2 months versus 4 months). The 1-year PFS was 47.3% compared to 7.2% in the placebo-treated group. Higher PFS and response rate with Cabozantinib was observed across all subgroups irrespective of RET mutation status (familial or sporadic) [73]. The long-term outcome of the trial at a minimum follow-up of 42 months showed 5.5 months increase in median OS with Cabozantinib; however, the difference was not statistically significant (hazard ratio (HR), 0.85; 95% confidence interval (CI), 0.64–1.12; $p = 0.24$) [74].

5 Anaplastic Thyroid Cancers

Anaplastic cancers are most aggressive thyroid cancers which arise de novo or due to transformation in a DTC. These tumors portend a poor prognosis, grow rapidly and usually present in advanced stage precluding surgery in the majority of cases. However, whenever the disease is confined to the thyroid gland and deemed operable, surgery should be aimed for. The median survival of these cancers is 3–5 months and the 10-year survival rate <5% [75].

6 Parathyroid Cancers

Parathyroid carcinoma is rare and accounts for 0.005% of all cancers [76]. Presenting symptoms are nonspecific and often mimic primary hyperparathyroidism with raised calcium and parathyroid hormone (PTH) levels posing a diagnostic challenge. About 10% of the parathyroid carcinoma may be nonfunctional. The disease affects both males and females equally unlike benign hyperparathyroidism which is more common in females. Patients typically present in the fifth decade which is 10 years earlier than patients with primary hyperparathyroidism. These cancers are initially indolent but progressive causing local invasion. Surgery forms the mainstay of treatment with some role of adjuvant radiotherapy. Given its rarity, the prognostic factors are less clearly defined making formulation of guidelines difficult.

6.1 Incidence and Epidemiology

The entity was first described in 1904 by Swiss surgeon Fritz De Quervain [77]. The disease is mainly sporadic and etiology largely unknown. Studies have suggested a possible role of radiation exposure, end-stage renal disease and parathyroid adenoma or hyperplasia; however, a strong causal association with these conditions is lacking. The disease may present as a part of genetic syndrome commonly associated with hyperparathyroidism jaw-tumor syndrome (HPJT), an autosomal disorder characterized by ossifying fibromas of the mandible and maxilla in addition to parathyroid carcinoma. Other syndromic associations are with multiple endocrine neoplasia (MEN) 1, and familial isolated hyperparathyroidism [78].

6.2 Clinical Presentation

The clinical symptoms are mainly a result of hypercalcemia and frequently mimic benign hyperparathyroidism. However, the severity of symptoms is significantly higher in parathyroid carcinoma. The common symptoms are weakness, lethargy, fatigue, depression, impaired memory, weight loss along with abdominal symptoms like pain, peptic ulcers and pancreatitis. Patients may also present with renal and skeletal symptoms which are more commonly associated with carcinoma. Nonfunctioning parathyroid carcinomas (10%) tend to present with an atypical clinical picture often misleading diagnosis [79]. These patients present late and usually with neck masses due to the primary disease or regional metastasis. Patients may also present with metastasis in as high as 30% of patients. Neck mass, RLN palsy or signs of local invasion should prompt the diagnosis in favor of malignancy as these are fairly uncommon in conditions of benign hyperparathyroidism [80–82].

6.3 Evaluation and Work-Up

Parathyroid carcinoma is usually associated with serum calcium levels over 14 mg/mL. Parathormone acts as a reliable tumor marker both to establish the diagnosis and early detection of recurrence. PTH is markedly raised 10- to 15-fold higher than the normal [83]. Imaging (ultrasound, 4D computed tomography scan and technetium 99 sestamibi scan) helps in locating the site and extent of disease. Cross-sectional imaging is preferred to assess the extent when the local invasion is suspected. FNAC is not useful in establishing the diagnosis and may lead to seeding of the track. Parathyroid carcinoma is usually diagnosed on histopathology, which may, however, be difficult at times with equivocal pathological findings. Local invasion and metastasis (regional/distant) are the fundamental features of malignancy. Schantz and Castleman criteria that consider five histopathological features namely presence of a trabecular pattern, mitotic figures, thick fibrous bands, capsular invasion and blood vessel invasion is widely followed to help establish a diagnosis [82]. Features of invasion on histopathology are the sine qua non of the malignancy.

6.4 Principles of Management

Parathyroid carcinoma is best managed by a multidisciplinary team which should include an endocrinologist. Hypercalcemia which is often severe (>14–16 mg) and needs control in the preoperative and postoperative period. Surgery is the mainstay of treatment which should aim for complete removal of disease. Outcomes are dictated by the experience and expertise of the treating team [84, 85]. Patients are therefore best treated at tertiary centers having a dedicated team to manage these cancers.

6.4.1 Surgical Management

Parathyroid carcinoma is a surgical disease and resection should encompass en bloc excision of the tumor with negative gross and microscopic margins [86]. Some centers recommend more extensive surgery including thyroid lobectomy However, there is a lack of evidence that extensive surgery offers a survival benefit. Young et al. in a study of 136 patients showed that the extent of surgery (parathyroidectomy compared to en bloc resection and delayed thyroidectomy) did not improve survival [87]. However, inadequate surgery results in recurrence; rates as high as 49% were reported after the initial cancer surgery [88]. The incidence of lymph node metastasis is low, and hence, routine central compartment clearance may not be necessary for the clinico-radiological/at surgery node-negative disease [89]. Hsu et al. reported a study of 405 parathyroid carcinoma patients in which 114 patients had lymph node examination. Only 10.5% cases showed regional metastasis which was 7.5 times more frequent with tumor size ≥3 cm. Regional metastasis, however, was not an independent predictor of disease-specific survival [90]. Intraoperative PTH assay is a useful adjunct at surgery as the majority of tumors are secretory and drop in the levels guide the adequacy of surgery [80, 85].

6.4.2 Radiation Management

Parathyroid carcinomas are relatively radioresistant, and hence, the role of definitive radiotherapy (RT) is limited. Adjuvant RT, however, offers decreased local relapse rates and better locoregional control but the survival benefit is uncertain [84, 85, 91]. A case series from MD Anderson showed that although RT is well tolerated in these patients, whether it is beneficial and time of administration remains unclear [92]. Another recently published large series from NCDB of 885 patients showed that RT was not associated with survival benefit [93]. A large NCDB study of 1022 patients showed that relative risk of death was increased with old age, secondary malignancy, positive margin and lymph node positivity. The study however did not support the role of adjuvant RT for survival benefit [94]. The adjuvant radiotherapy should therefore be considered in presence of factors associated with high risk of locoregional recurrence like gross soft tissue invasion by disease, positive margins, nodal metastasis and recurrent cases.

6.4.3 Medical Management

There is no robust data to support the role of systemic therapy in parathyroid carcinoma. Literature is mainly contributed by anecdotal case reports and small series making interpretation difficult. The overall results have been unsatisfactory with chemotherapy and there is no standard regimen followed for the treatment of these tumors. Monotherapy using dacarbazine or combination of drugs fluorouracil, cyclophosphamide and dacarbazine or methotrexate, doxorubicin, cyclophosphamide and lomustine have shown some benefit in case reports [79, 81, 83].

6.5 Stage-Wise Prognosis with Current Treatment

AJCC 8th edition stages parathyroid carcinoma based on the extent of invasion of the primary tumor to the surrounding structures and not on the size, level of lymph node involvement and distant metastasis. The staging system however is premature as it is based on small retrospective studies with wide variation [95]. These are relatively indolent tumors with a reported 5- and 10-year OS of 86% and 49%, respectively [76].

6.6 Management of Recurrent Disease Including Specific Palliative Measures

Patients with surgically unresectable disease, recurrence and distant metastasis frequently develop hypercalcemic crisis. The medical challenge is to control the serum calcium level which otherwise can be fatal. Patients present with altered mental status and weakness as the result of hypercalcemia leading to excessive fluid loss secondary to vomiting and increased diuresis. Intravenous saline hydration with loop dietetics is the first essential step of treatment. Calcimimetic agents like cinacalcet, acting on a calcium-sensing receptor on the parathyroid gland and drugs blocking the osteoclast-mediated bone resorption like calcitonin and bisphosphonates help in decreasing serum calcium levels. There are studies to suggest the use of ethanol injections to ablate the unresectable disease and palliate symptoms but are not the routine standard of care [96].

7 How Do We Do It at TMC

7.1 Differentiated Thyroid Cancers

- Thyroid function test is the first investigation to be performed.
- Patients with clinical or subclinical hyperthyroidism undergo radionuclide scan and treated for the same.
- Other patients are evaluated further using USG. The reporting is done as per TIRADS and thyroid multimodal-imaging comprehensive risk stratification scoring (TMC RSS) [97].
- FNAC is performed for nodules >1 cm with high and intermediate, 1.5 cm with low and ≥2 cm with very low suspicion USG pattern.
- When extrathyroidal extension is suspected cross-sectional imaging is performed. CECT is also performed for node mapping as an adjunct to ultrasonography.
- Surgery is the mainstay of treatment which is hemithyroidectomy for nodules intraparenchymal ≤1 cm, total thyroidectomy >4 cm, hemi or total thyroidectomy between 1 and 4 cm based on high-risk factors or patients' preference.
- Therapeutic neck dissection in presence of regional metastasis.
- Role of prophylactic neck dissection in select cases.
- RAI ablation for high and intermediate risk DTC.
- Administration of supraphysiological doses of thyroxine for DTC. The TSH is to be maintained between 0.5–2, 0.1–0.5 and <0.1 mU/L in low, intermediate and high-risk patients.
- Follow-up frequency based on risk stratification with clinical examination, ultrasonography, serum Tg and RAI scan if indicated.

7.2 Medullary Thyroid Cancers

- Establishment of diagnosis: FNAC, serum calcitonin.
- Extent of disease: PET scan or CECT neck and thorax and triple phase CECT abdomen.
- Establishment of familial MTC: genetic testing to detect germline RET mutation; if positive then genetic counseling and screening for pheochromocytoma with plasma free metanephrines and normetanephrines.
- Minimum surgery in MTC is total thyroidectomy with central compartment clearance.
- Therapeutic neck dissection in patients with regional metastasis.

Fig. 1 Management of thyroid enlargement: work-up and treatment

- Prophylactic neck dissection based on the serum calcitonin level in node negative neck.
- Prophylactic total thyroidectomy for germline RET mutation positive siblings and first degree relative.
- Administration of thyroxine to maintain TSH within normal range.
- Follow-up with clinical examination, ultrasonography and serum calcitonin 3 monthly.
- Hereditary cases showed by followed up for pheochromocytoma and hyperparathyroidism.

7.3 Anaplastic Thyroid Cancers

- If operable, then surgery.

7.4 Parathyroid Carcinoma

- Raised serum calcium and PTH levels along with signs of hypercalcemia suggest the probability of PTH carcinoma.
- Surgery for parathyroid cancer is en bloc resection of parathyroid gland with negative gross and microscopic margins. Ipsilateral lobectomy and excision of adjoining structures if involved by disease, appropriate neck dissection.
- Serum PTH is a reliable tumor marker to detect recurrence in follow-up.

A management algorithm is presented in Fig. 1.

1 Introduction

Breast cancer is the commonest cancer in Indian women [1] with the age-adjusted incidence rate and mortality per 100,000 women of 25.8 and 12.7, respectively [2]. The incidence is different in urban and rural India, with one-third in urban areas and one-ninth in rural areas [3]. Overall, the stage distribution ranges from 40% to 50% for early, 30% to 40% for locally advanced and 5% to 10% for metastatic setting [1]. Early dissemination of the breast cancer cells provides rationale for adjuvant systemic therapy which substantially reduces the risk of distant recurrence and breast cancer mortality.

2 Predictive and Prognostic Markers

Prognostic factors are surrogate markers of the aggressiveness that provide information on the inherent biological behavior of the disease in the absence of any type of adjuvant systemic treatment.

The most significant clinicopathologic prognostic factors [4] include stage (determined by the tumor size and extent of axillary lymph node involvement) [5] and histologic grade (assessed by the Nottingham method or the Elston–Ellis modification of the Scarff–Bloom–Richardson system) [6]. Young age at presentation, menopausal status, presence of lymphovascular emboli and extracapsular nodal extension form independent adverse prognostic factors [7–10]. Ki67 expression, a marker of tumor proliferation, impacts disease-free survival [11]. Mitotic index has been found to be a

strong predictor of survival in node-negative breast cancer patients [12].

Predictive factors are indicative of response of the tumor to specific therapies and therefore can help guide treatment management. Steroid hormone receptors were originally classified as markers with prognostic significance but lost this advantage with prolonged follow-up [13]. Steroid hormone receptors (ER/PR) are predictive markers in the adjuvant setting and HER2/neu receptor is both a strong predictive and prognostic marker. HER2 status is predictive of response to anti-HER2-targeted therapies like Trastuzumab and Pertuzumab [14]. Recent evidence also suggests increased sensitivity of HER2+ tumors to anthracycline-based chemotherapy [14].

Ki67 (marker of proliferation) is a nuclear antigen, which is both a prognostic and predictive factor in early breast cancer, and is used to decide response to chemotherapy [15]. A higher nuclear grade and overexpression of p53 [16] has a direct correlation with higher Ki67. A number of studies [17, 18] have reported that a higher Ki67 index correlates with larger T size, positive lymph nodes and lymphovascular invasion. The variability of correlation may be attributed to the cut off values for Ki67, as Ki67 has been divided based on ≥10% and <10% in some studies and in other studies based on ≥20% and <20%.

Gene signature panels are available like the *Oncotype DX* (21-gene assay) [19], *Mammaprint* (70-gene profile) [20, 21], *Breast Cancer Index* (two gene recurrence score and a five gene tumor molecular grade index) [22, 23] and *Prosigna* (50-gene classifier) [24]. They provide prognostic information over and above standard factors and direct evaluation of the risk–benefit ratio of adjuvant systemic therapy for node-negative breast cancer. The OncotypeDX RS assay is useful as a decision-making tool in node-negative hormone receptor-positive breast cancer patients [25] and even in some 1–3 LN-positive cases [26].

Online tools are available to prognosticate the disease and aid clinical decision making with respect to adjuvant therapy. *Adjuvant! Online* provides estimates of the risk of disease recurrence or death at 10 years [27]. *Predict* calculates the relative reduction in mortality with multiple lines of chemotherapy and hormone therapy [28]. Validation of these online tools in specific geographic locations is needed before routine use, due to possible differing biological characteristics compared to the original validation cohorts.

3 Principles of Management

3.1 Early and Locally Advanced Breast Cancer

Surgery is the mainstay of treatment. Over the years, the original Halstedian theory has given way to Fisher's theory that breast cancer is a systemic disease at inception. This has led to a paradigm shift toward conservation in locoregional treatment with the advances in systemic therapy. The principle of loco regional therapy is based on eradication of all malignant cells from the breast and the draining nodal basin. Adjuvant therapy includes systemic chemotherapy followed by radiation and hormonal therapy. The goal of systemic therapy is eradication of the microscopic disease present in the body in the form of occult metastasis. There are various lines of chemotherapy which can be used in combination with targeted therapy. Radiation helps to achieve loco regional disease control.

3.2 Metastatic Breast Cancer

The goal of treatment is disease control and palliation of symptoms. For hormone receptor positive with low disease burden, endocrine therapy can be started as the first-line treatment. There is good response observed in approximately 30% to 40% patients with disease stabilization in another 20% [12]. If the disease burden is high, systemic therapy is indicated with maintenance hormone therapy. If HER2/neu is overexpressed/amplified, anti-HER2-targeted therapy agents are also indicated. Bisphosphonates are added for bone metastasis. Surgery is reserved for bleeding or fungating tumors [29]. Radiation is used for metastatic sites in the bone or brain or occasionally a bleeding tumor in an unfit patient.

4 Imaging

4.1 Screening

The role of mammography as a screening tool has been criticized over the years. Sensitivity of mammography in a premenopausal population is low and efficacy as a screening tool has been debatable. In women above 50 years of age, mammography has shown a reduction in mortality, but at the cost of increase in the over-diagnosis of approximately 25% after 25 years of follow-up [30]. In contrast, CBE results in minimal over-diagnosis as shown in the randomized studies on CBE versus not. In the studies evaluating CBE as a single modality, all cancers detected were invasive or palpable preinvasive tumors.

4.1.1 Current Status of Screening for Breast Cancer

The US Preventive Services Task Force recommendations for screening suggest performing a mammogram every 2 years in women aged 50–74 [31]. The updated results of the age trial have however indicated some additional benefit of screening for women aged 40–50. The updated results of the AGE trial suggested reducing the lower age limit for screening from 50 to 40 years could potentially reduce breast cancer mortality, though most cancers were identified in women after 50 even in that trial [32]. Additionally, clinical breast examination conducted biennial, results in down staging and reduces mortality by 30% in women over the age of 50 years [33].

Screening recommendations for breast cancer are listed in Table 1.

Table 1 Screening recommendations for breast cancer

- Awareness and breast self-examination as a tool for awareness in woman of all ages.
- Not enough evidence to support screening mammogram in women <50 years of age.
- For premenopausal women, awareness of breast cancer.
- Annual clinical breast examination and awareness about breast cancer of biennial mammography in healthy women over the age of 50 years.
- However, the 25% probability of overdiagnosis must be kept in mind when recommending mammography as a screening tool.
- High-risk individuals (BRCA-positive, significant family history) to be treated as per standard guidelines.

Abnormalities detected on screening mammograms will often be nonpalpable lesions like microcalcifications, masses or focal areas of architectural disturbance (Fig. 1). Some of these lesions may be seen on correlative ultrasound, which helps in targeting the biopsy. USG-guided biopsy is a real time biopsy that is more comfortable for the patient and is preferred if the lesion is identified on USG (Fig. 2). For the abnormalities that are seen only on mammograms, vacuum assisted biopsy (VAB) devices are able to obtain almost complete excision of small lesions under stereotactic guidance. Another method is hook wire localization, either with stereotaxy or manually, followed by complete excision of the area of abnormality (Fig. 3). VAB is expensive; however, it is fully done under guidance while the hook-wire excisions require coordination between the mammography and surgical teams.

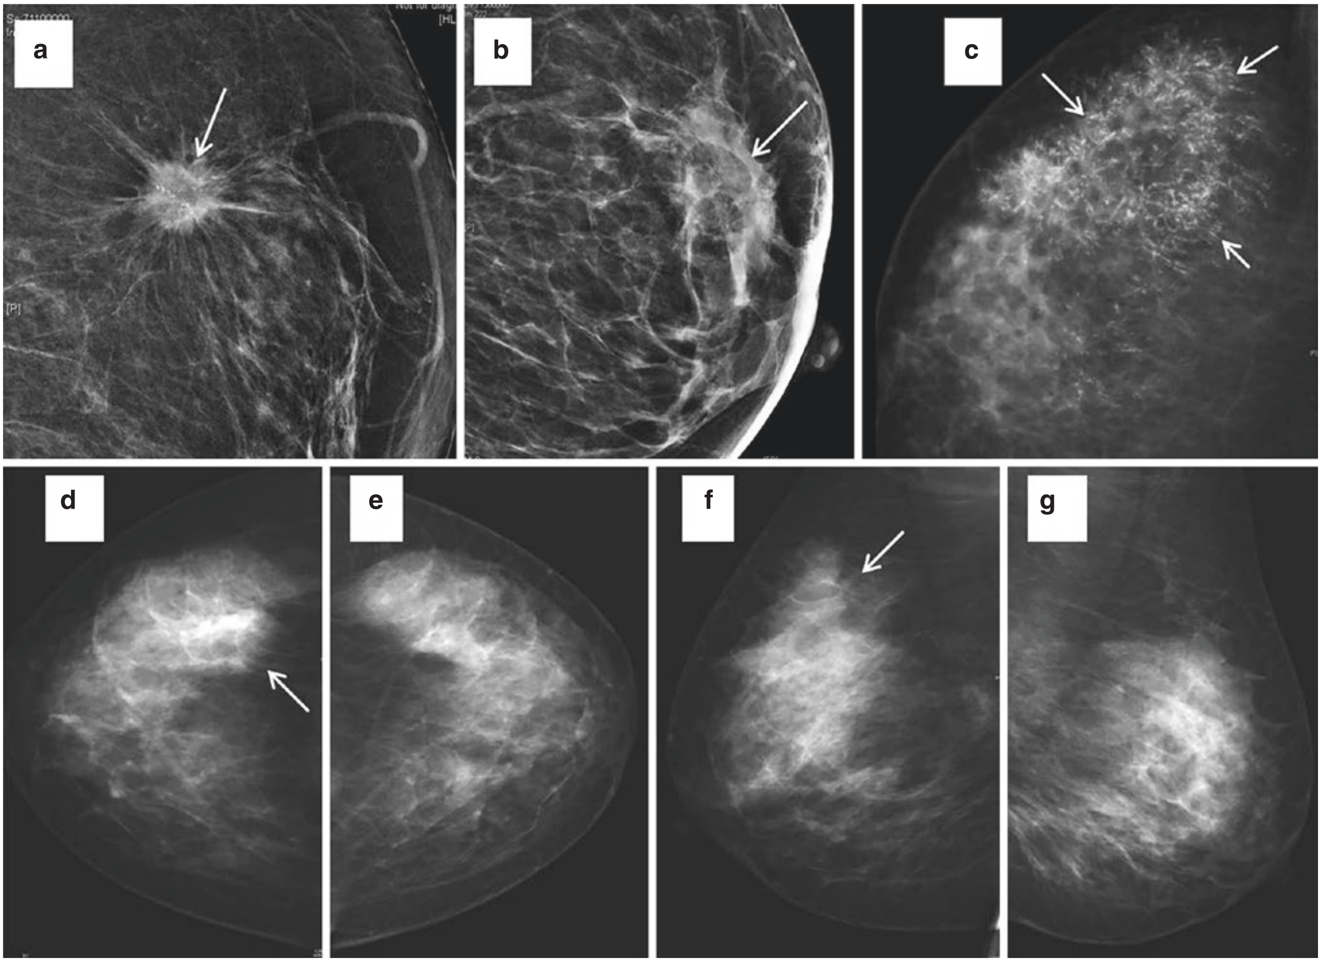

Fig. 1 Types of manifestations of breast cancer on mammograms. (**a**) A classical spiculated mass with microcalcifications (arrow). (**b**) An area of architectural distortion (arrow). (**c**) Regional pleomorphic microcalcifications (outer limits marked by arrows). (**d**) Right CC, (**e**) left CC, (**f**) right MLO and (**g**) left MLO views of the same patient showing asymmetric increased density in the right upper outer quadrant marked by arrows. This was caused by a mass

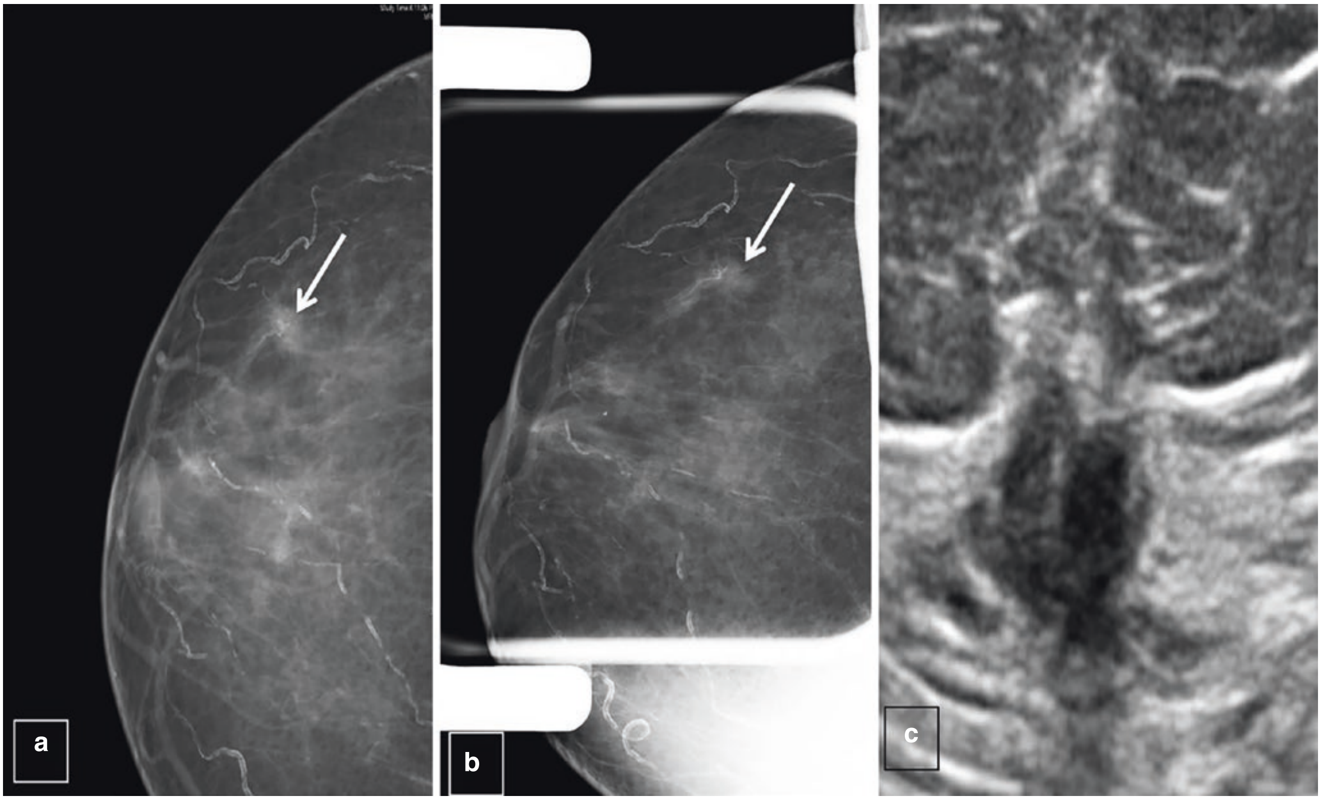

Fig. 2 In the screening craniocaudal view of the mammograms (**a**) a small irregular density is seen which is first confirmed by a spot compression view (**b**) and also seen as a hypoechoic solid mass with irregular shape and irregular margins on the ultrasonography images (**c**). The lesion can then be sampled for histopathology under ultrasound guidance

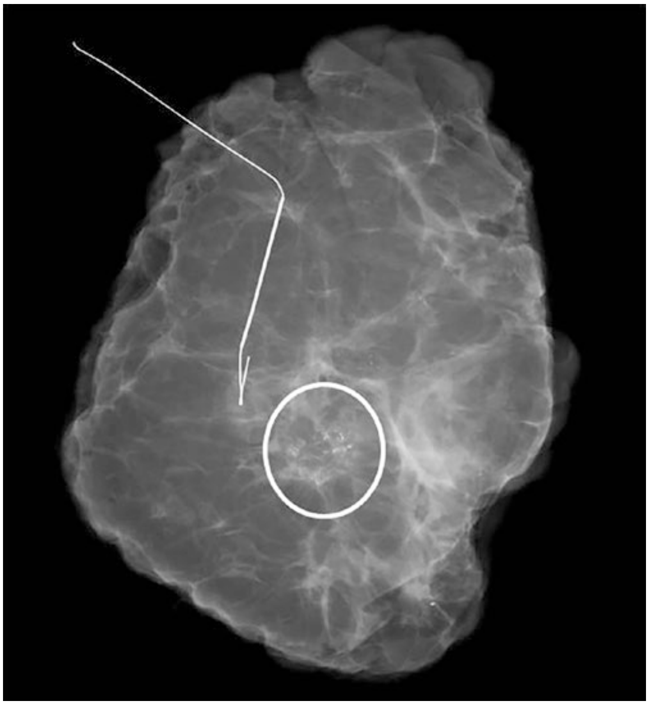

Fig. 3 Specimen radiograph showing pleomorphic microcalcifications (encircled) with a hook wire adjacent to them

4.2 Diagnostic Imaging

The current role of mammography is diagnostic, to evaluate the ipsilateral breast for number of lesions and to help map the extent of disease (if the woman is keen on breast-conserving surgery) and to screen the opposite breast at the time of surgery (less than 4% women may have a contralateral lesion). The sensitivity of mammogram depends on the breast density on mammogram (Fig. 4).

A combination of MG and USG can detect additional lesions than either of them alone but USG has a high false-positive rate [34]; hence, it is not routinely recommended in all patients. It can be used in cases when there the breasts are dense and the mass is occult or when there is clinical suspicion of multiple tumors. USG also serves as an adjunct for characterization of the mass, especially to differentiate a cystic one lesion from solid. MRI is not recommended as a preoperative test for evaluation of ipsilateral breast in all patients diagnosed with breast cancer, even when a breast conservation surgery is planned. The COMICE trial a randomized controlled trial (RCT) that showed that no benefit with the addition of MRI to triple assessment in patients undergoing BCT [35]. The MONET trial demonstrated adverse effect of

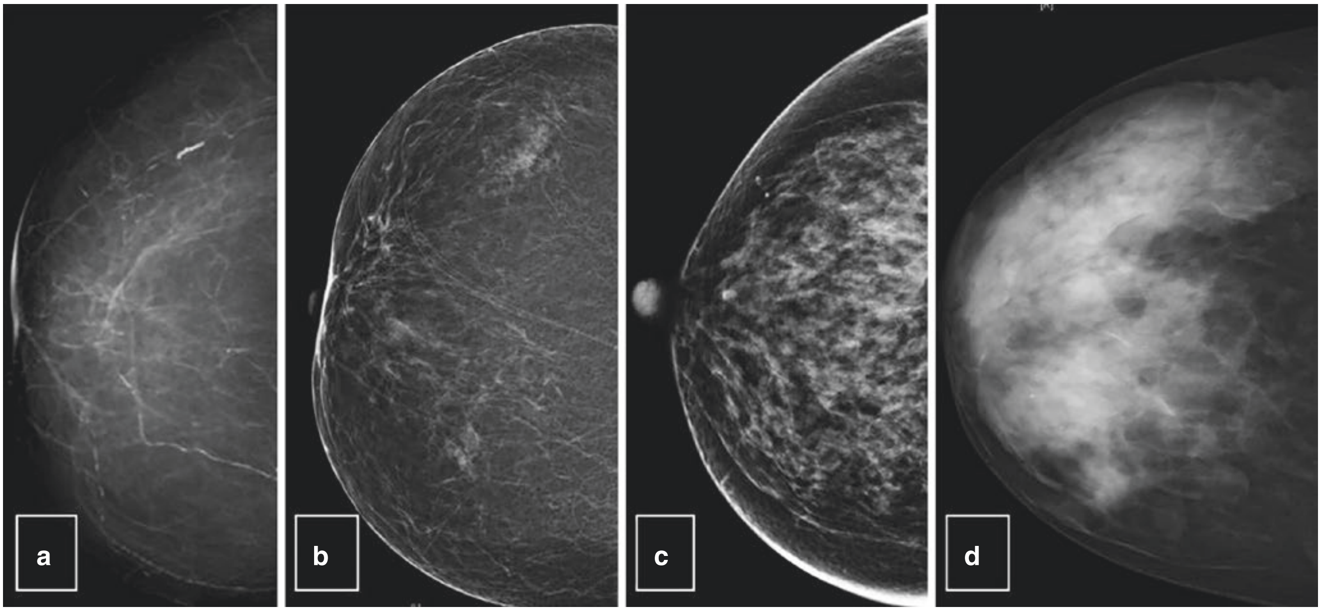

Fig. 4 This composite image illustrates the different types of normal breast parenchyma, with images from left to right showing increase in proportion of fibro-glandular tissue which leads increasing breast density. The sensitivity of mammography decreases with increasing breast density. (**a**) fatty breast, (**b**) scattered fibroglandular density, (**c**) heterogeneously dense, (**d**) extremely dense

MRI in the form of increased re-excision rates in patients undergoing MRI [36].

Housammi et al. in an individual patient data meta-analysis evaluating the association between preoperative breast MRI and local and distant recurrence in patients with breast cancer suggested that preoperative MRI is not associated with reduced risk of local or distant recurrence, at 8-year recurrence-free survival [37]. However, MRI breast may be considered when the diagnosis of lobular carcinoma is made as there is an increased incidence of multifocal/bilateral tumors. MRI is also useful in cases such as those with Paget's disease with dense breast on mammograms and no identifiable primary, metastatic axillary adenopathy and negative dense mammograms (EUSOBI guidelines).

5 Surgical Management

5.1 Management of Primary

Surgical management has evolved from the era of Halstedian radical mastectomy to lumpectomy and breast conservation. There has been a paradigm shift toward conservation, both of the primary and the axilla.

Landmark studies like NSABP B-06 compared mastectomy to lumpectomy with or without radiation. Cumulative incidence of IBTR was 39.2% for the lumpectomy alone arm and 14.3% for the lumpectomy with RT arm ($P < 0.001$) [38]. We have now shifted to an era of oncoplastic breast surgery.

Oncoplastic surgery (OPS) allows for wide excision without compromising principles of oncology and integrates plastic surgery techniques for immediate breast reshaping. Oncoplastic techniques range from simple reshaping and mobilization of breast tissue to more advanced mammoplasty techniques. With improving survival, cosmetic outcome and quality of life have come to the forefront and the future of surgery for breast cancer lies in integrating principles of OPS into our practice.

The selection of the oncoplastic surgical technique is based on numerous factors, for example patient's breast size, lesion location and volume of breast tissue excised (Table 2).

Local recurrence: In conventional breast-conserving surgery (BCS) local recurrence rates are reported between 10% and 14%, while in oncoplastic surgery, rates are documented at 2% and 9%. The possible explanation is that OPS usually entails wider excision. Rainsbury [39] reported local recurrence for volume displacement to be 0% to 7%, and of volume replacement to 0% to 5%. Clough et al. [40] reported local recurrence rate of 9.4% with OPS (Table 3).

Breast reconstruction: The decision about breast reconstruction (BR) is often multifaceted, including patient perceptions and surgeon expertise and available donor sites. In a large survey conducted among patients treated for breast cancer who had undergone a mastectomy, 20% said they would consider secondary reconstruction. The remaining patients possibly have high coping skills or are satisfied with the external prosthesis [41].

Post chemotherapy BCS: Breast conservation for locally advanced tumors is an option in well selected cases as is

Table 2 Classification of oncoplasty

Based on timing

Depending upon when the plastic surgical procedure is carried out, there are three options:

1. Immediate—At the time of primary surgery
2. Delayed immediate—1–2 weeks following primary surgery (usually after histopathological confirmation)
3. Delayed—Anytime following radiation

Based on technique

Oncoplastic procedures, for convenience, are divided as

1. Volume displacement procedures
2. Volume replacement procedures

Table 3 Risk factors for local recurrence following BCT

These factors can be divided into patient-, tumor- and treatment-related factors

Patient-related factors:

1. Age
2. Inherited susceptibility: presence of hereditary breast and ovarian cancer syndromes

Tumor-related risk factors:

1. Positive resection margins
2. Molecular subtypes
3. Treatment-based risk factors
4. Use of boost to the tumor bed
5. Adjuvant systemic therapy

shown by the various prospective and retrospective cohort studies [42]. The recent EBCTCG review on BCS post NACT highlights the importance of accurate localization techniques pre NACT to mark the tumor bed appropriately [43].

5.2 Approach to Axilla

Management of axilla has evolved from complete axillary dissection to sentinel node biopsy. Axillary lymph node dissection (ALND) remains the standard for patients with node-positive disease (with histologic confirmation). A complete axillary dissection is still carried out in most node-positive cases. A clinicoradiologically node-negative axilla has a 30% to 40% possibility of harboring occult metastatic disease [44]. National Comprehensive Cancer Network guidelines recommend to clear level I and II of the axilla [45]. However, in cases with 4 or more positive axillary LN, the probability of positive level III LN was as high as 53.2% [46]. Almost 50% of patients with high level I and II nodal burden run the risk of having residual disease in the axilla after surgery if level III is not addressed.

Axillary conservation: NSABP B-32 was a randomized trial that demonstrated the safety of avoiding ALND when the sentinel node is negative. Following this landmark study, sentinel lymph node biopsy (SLNB) is the standard procedure in clinically node-negative cases [47]. A validation study carried out for "low axillary sampling" (LAS) by Parmar et al. at TMH in 478 women with clinically N0 axilla yielded a false-negative rate (FNR) of 10.5% for LAS compared to 12.7% for SLNB [48]. In a resource constrained setting, LAS can be used as an acceptable alternative to SNB (Fig. 5).

1–2 LN positive: Women with SLN-positive breast cancer can either be considered for complete axillary dissection, or in cases of 1–2 LN positive can be considered for no further treatment to axilla or axillary radiotherapy [49, 50].

The results from the ACOSOG Z0011 [49] trial concluded that women with T1–T2, breast cancer, who had 1 or 2 positive SLNs, and were treated adjuvant systemic therapy and whole breast irradiation could be spared an ALND. However the study enrolled a large proportion of on pT1, low grade, micometastatic LN-positive patients. A similar audit reported from an Indian cohort, reported less than 10% of patients treated a tertiary cancer center [51] were similar low-risk disease and the authors recommend caution in extrapolating the results of the ACOZOG Z0011 trial to the general population of 1–2 SLN-positive EBC.

Multiple studies [52, 53] have evaluated risk factors for NSLN metastasis, including T size, grade, number of positive SLN, macrometastases and lymphovascular invasion and extranodal involvement.

Postchemotherapy axillary conservation: The role of conservative axillary surgery is not as robust in the post-chemotherapy situation. Numerous trials [54–57] have evaluated the role of SLN/LAS in the post NACT setting and current recommendations include the use of targeted axillary dissection, more than 3 SLN identified and dual dye technique [58].

Stage-wise management algorithms are presented in Figs. 6, 7, 8 and 9 [59].

6 Role of Radiotherapy

6.1 BCS

The Early Breast Cancer Trialists' Collaborative Group (EBCTCG) meta-analysis for breast conservation has shown that adjuvant RT reduces the absolute 10-year risk of local recurrence by 15.4% and 21.2% and 15-year risk of breast cancer mortality by 3.3% and 8.5%, respectively, in node-negative and node-positive women [60]. Following BCS, adjuvant RT to the whole breast with or without boost to the tumor bed is warranted in all patients.

It is prudent to deliver additional dose to the tumor bed as the long-term results of the large EORTC 22881-10882 trial have shown that a sequential 16 Gy boost to the tumor bed following 50 Gy to the whole breast confers improved local control across all age groups with maximum absolute benefit observed in women younger than 40 years (20-year risk 36.0% vs. 24.4%) [61]. However, boost also results in significant increase in the rates of severe fibrosis with a 10-year rate of 4.4% versus 1.6% when boost is not given ($P < 0.0001$).

6.2 Postmastectomy

For patients undergoing upfront MRM for early breast cancer, adjuvant RT is advised for patients with ≥4 positive lymph nodes irrespective of tumor stage. The recently conducted meta-analysis by EBCTCG showed that postmastectomy radiotherapy (PMRT) results in significant reduction of locoregional relapse (RR 0.68 for 1–3 nodes and RR of 0.79 in >3 positive LNs) as well as mortality (RR 0.80 for 1–3 LN and RR 0.87 for >3 positive LNs) [62].

6.3 Regional Lymph Node Irradiation

6.3.1 Axilla

The management of axilla has seen a major paradigm shift with a trend toward an axillary sparing approach to minimize morbidity in both patients with negative axilla as well as in case of limited positivity. The AMAROS and ACOZOG Z-11 study support the use of axillary radiation therapy in patients with SNB positive who have not undergone ALND [49, 50]. However, these studies include most patients with low-risk cancers with micrometastatic lymph nodes.

6.3.2 Other Regional Sites

Recently published studies like the MA 20 [63] and the EORTC 22922 [64] support comprehensive regional nodal irradiation but do not clarify as to which nodal region contributed toward maximum benefit. The benefit of treating nodal regions in a clinically T3N0 patients is not reported directly and current institutional practice is to treat supraclavicular region with RT for all locally advanced breast cancers. Internal mammary nodal chain is included if it is radiologically proven to harbor metastases prior to initiating any cancer directed treatment. Inclusion of extensive lymph nodal regions increases the risk of normal tissue toxicity and compels usage of complex techniques to achieve acceptable dose distribution.

6.4 Dose Fractionation

Hypo-fractionation implies delivery of fewer and larger doses of radiation (with a lower total dose). Mature results of the large phase 3 randomized trials from England and Canada and their meta-analysis not only confirmed the equivalence of hypofractionated regimen to the conventional regimen (comprising of total dose of 45–50 Gy in 25 fractions over 5 weeks with daily dose of 1.8–2.0 Gy per fraction) for local control but also reported that breast shrinkage, telangiectasia and breast edema were significantly less frequent with the hypo-fractionated regimen [65]. The ASTRO has also recently updated their guidelines on the use of hypofractionation for whole breast RT [66].

Recent Publication from the UK-FAST (28.5 Gy arm) and the FAST-Forward (26 Gy arm) studies show that 5 fraction RT either delivered once a week or daily is equivalent to the 5 or 3 weeks conventionally fractionated and moderately hypofractionated regimen [67, 68] respectively. The UK-FAST study included low-risk, hormone receptor-positive, node-negative patients older than 50 years who did not merit tumor bed boost. However, the UK-FAST Forward study was a pragmatic trial that included all patients T1–T3 and N0–1. The recent publication has only reported the safety and 5-year clinical outcomes for node-negative patients. As per the acute toxicity data on daily 5-fraction regimen, patients undergoing daily 5-fraction RT tend to develop acute toxicities 2 weeks after treatment completion. However, the grade of all the toxicities are similar except higher induration outside the tumor bed [1.90 (1.15–3.14), $P = 0.013$]. The 5-fr regimen can be adopted safely for low-risk node-negative patients at centers with appropriate quality assurance program as required by the study. This will help to improve access and ease of receiving RT and subsequently improve the breast conservation rates especially among lower and middle-income countries.

6.5 Accelerated Partial Breast Irradiation (APBI)

In optimally selected women, this can be accomplished by various means like brachytherapy (interstitial or balloon), external beam techniques (electrons, 3DCRT, IMRT, IGRT, protons) or intraoperative RT [69]. Due to the diversity of inclusion criteria, sample size, techniques and dose fractionation regimes used in various randomized studies, the efficacy and toxicity results vary considerably. Interstitial brachytherapy is the safest technique as this has been proven to be noninferior and less toxic to conventional whole breast RT in a large European phase 3 trial and is supported by long-term outcome from various institutional series [70–72].

Table 4 presents radiotherapy guidelines for early breast cancer.

Table 4 Radiotherapy guidelines for early breast cancer

RT type	DCIS	OBC (T1/2; N0/1)	
		pT1/2 pN0	pT1/2 pN1
No RT required	Postmastectomy	(A) Highly select as per PRIME study criteria (grade 1–2, T1–T2 up to 3 cm especially in estrogen rich tumors)	X
Tumor bed + margins after BCT	After BCT in almost all cases unless the tumor low grade and ER positive allowing for endocrine prophylaxis	(B) APBI in select cases (ESTRO low and intermediate risk groups) (C) Boost in all cases except small low grade tumors in elderly as in EORTC trial	In all cases
Whole breast after BCS	For all patients	In all cases except (A) and (B)	In all cases
Chest wall after MRM	X	Under clinical trial setting	In all cases except select pN1 cases like grade 1 with T1 disease
Supraclavicular fossa	X	X	In all cases except select pN1 cases like grade 1 with T1 disease
Axilla	X	X	If SNB/AS positive and axilla not cleared
Internal mammary	X	X	X

6.6 Role of Radiation Therapy in Metastatic Breast Cancer

6.6.1 Bone Metastases (BM)

Radiation therapy provides effective palliation in majority of the patients of painful bone metastases with few side-effects [73]. Patients experience an improvement in their QoL, reduced analgesic requirements and maintenance or amelioration of skeletal function. Numerous studies have proven that single-fraction radiation therapy (SFRT) is equally effective for pain control and fracture risk as compared to multiple fraction palliative RT. Therefore, SFRT appears to be a more convenient fractionation as it reduces the treatment and travel time. However, patients undergoing SFRT have a higher retreatment rate which has to be discussed with the patient expected to have longer survival [74].

6.6.2 Brain Metastases (Brm)

Stereotactic radiosurgery (SRS) is an established noninvasive ablative therapy for patients having limited number (1–5) of brain metastases with a cumulative volume up to 20 cm^3. Randomized studies evaluating the role of SRS alone versus WBRT with SRS have shown no difference in the overall survival while those who received WBRT + SRS had greater cognitive decline and poor quality of life [75]. SRS alone has been shown to have higher local and distant brain failure (30%–70%) which may be treated with multiple sessions of SRS or salvage WBRT [63]. A meta-analysis favored treatment of younger patients (≤50 years) with SRS in view of better survival [76]. Treatment with SRS is technically challenging and coupled with a rigorous imaging follow-up schedule to detect new sites of metastases early for appropriate salvage therapies. SRS can be offered preoperatively or postoperatively as the only study that compared the two approaches did not find a difference in the survival end points. However, postoperative SRS had significantly higher rates of leptomeningeal disease, radiation necrosis and symptomatic radiation necrosis complications [77]. However, WBRT should be offered to patients having extensive disease and in patients with limited life expectancy.

Systemic Therapy

Multiagent chemotherapy is an important modality of care to improve outcomes. The benefit of adjuvant chemotherapy (ACT) is proven for both high-risk (high grade, lymph node positive) as well as lower-risk patient population [78].

The 2012 EBCTCG meta-analysis demonstrated efficacy of adjuvant chemotherapy and tamoxifen in reducing the risk of recurrence and mortality across all the age groups [79].

7 Regimen Selection and Administration

The choice of a regimen depends on both patient characteristics as well as disease biology. The standard of care is anthracycline-taxane-based therapy. As per the 2012 EBCTCG meta-analysis, AC is at least equivalent to an alternative nonanthracycline-based regimen, CMF [78]. Taxanes in addition to anthracycline-based chemotherapy improved outcomes, including recurrence, and cause specific and overall mortality. The increment was irrespective of age, tumor size, tumor grade, nodal positivity and estrogen receptor (ER) positivity [69]. Furthermore, sequential treatment with anthracycline-based regimen followed by taxanes (e.g., AC then T) was associated with improved outcomes [80].

"Dose-dense" adjuvant treatment, in which treatment is given more frequently than the historical 3-week schedule, is associated with better DFS outcomes, shortened cumulative time of treatment and similar tolerability compared with standard dosing. It is typically administered on an every week or every 2-week schedule [81].

The institutional standard regimen for most patients who require chemotherapy is doxorubicin and cyclophosphamide (AC) followed by paclitaxel (T), sometimes known as AC-T. In high-risk and fit patients, it is given on a dose-dense schedule [81].

In women with endocrine-positive, HER2-negative, axillary node-negative disease, who had a low (10) and intermediate (11–25) 21-gene recurrence score (RS), adjuvant endocrine therapy with or without systemic chemotherapy had similar results. However, there was a small benefit of chemotherapy noted in women with 50 years of age or younger with a recurrence score of 16 to 25 [82].

Table 5 is a summary of adjuvant chemotherapy trials, and Table 6 presents recommended adjuvant chemotherapy regimens.

7.1 Neoadjuvant Systemic Therapy

Most patients with locally advanced breast cancer (LABC) need neoadjuvant systemic therapy to induce a tumor response before surgery and enable breast conservation. Regimens that are suggested for adjuvant treatment can also be employed in the neoadjuvant setting.

In the neoadjuvant context, the following approach may be recommended.

- Current research suggests that patients with hormone receptor-positive LABC should get neoadjuvant chemotherapy (NACT) rather than endocrine treatment to attain higher response rates in a shorter span.

Table 5 Summary of adjuvant chemotherapy trials

Comparison (reference)	Number of patients	Median follow-up (years)	Nodal status	Hazard ratio for disease-free survival	Hazard ratio for overall survival
CMF vs. no chemo [4]	386	28.5	Positive	0.71 ($P = 0.005$)	0.79 ($P = 0.04$)
CMF + Tam vs. Tam (B20)[5]	2306	5	Negative	0.65 ($P = 0.001$)	0.64 ($P = 0.03$)
AC vs. CMF (B15) [6]	2194	3	Positive	$P = 0.5$[a]	$P = 0.8$[a]
AC vs. CMF (B23) [7]	2008	5	Negative	$P = 0.9$[a]	$P = 0.4$[a]
FEC50 + Tam vs. Tam [8]	457	9.4	Positive	0.46 ($P = 0.0008$)	0.65 ($P = 0.07$)
FEC100 vs. FEC50 [9]	546	5.6	Positive	0.63 ($P = 0.02$)	0.45 ($P = 0.005$)
DCx4 vs. ACx4 [10]	1016	7	0–3 Positive	0.74 ($P = 0.033$)	0.69 ($P = 0.032$)
DAC vs. FAC [11]	1491	10.3	Positive	0.80 ($P = 0.004$)	0.74 ($P = 0.002$)
DAC vs. FAC [12]	1060	6.4	Negative	0.68 ($P = 0.01$)	0.76 ($P = 0.29$)
FAC-weekly T vs. FAC [14]	1925	5.3	Negative	0.73 ($P = 0.04$)	0.79 ($P = 0.31$)
FAC-weekly T vs. FAC [14]	2005	5.8	Positive	0.80 ($P = 0.01$)	0.85 ($P = 0.04$)
AC-T vs. AC-weekly T [15]	4954	12.1	Positive	0.84 ($P = 0.011$)	0.87 ($P = 0.09$)
AC-T vs. AC-D	5351	6.1	Positive	0.79 ($P = 0.001$	0.86 ($P = 0.054$)
AC-D vs. DAC [16]				0.83 ($P = 0.01$)	0.86 ($P = 0.09$)
AC-D vs. AD				0.80 ($P = 0.001$)	0.83 ($P = 0.03$)

AC doxorubicin, cyclophosphamide, *CMF* cyclophosphamide, methotrexate, 5-Fluorouracil, *DC* docetaxel, cyclophosphamide, *FAC* 5-Fluorouracil, doxorubicin, cyclophosphamide, *DAC* docetaxel, doxorubicin, cyclophosphamide, *FEC50* 5-Fluorouracil, epirubicin (50 mg/m^2), cyclophosphamide, *FEC100* 5-Fluorouracil, epirubicin (100 mg/m^2), cyclophosphamide, *D* docetaxel, *E* epirubicin, *T* paclitaxel

[a] Hazard ratios were not reported in the manuscript; however, *P* values did not reveal any statistical significance between study arms

Table 6 Recommended adjuvant chemotherapy regimens

Recurrence risk category	ER-positive, HER2-negative	ER/PR-negative, HER2-negative	HER2-positive
Very low risk			
• Node-Neg, T1a	No chemotherapy	No chemotherapy	No chemotherapy
Low risk			
• Node-Neg, T1b	DCx4 or ACx4 (ifRS is high)	DCx4 or ACx4	Weekly paclitaxel + H
• Node-Neg, T1c	DCx4 or ACx4 (if RS is high or mid-range with age <50)	DCx4 or ACx4	Weekly paclitaxel + H or TCH
Moderate risk			
• Node-Neg, T2	DCx4 or ACx4 or AC-T (ifRS—high range or mid-range with age <50)	AC-T	AC-T + H or TCH ± P
High risk			
• 1+ Posnodes or T3	AC-T	AC-T	AC-T + H or TCH ± P

AC doxorubicin, cyclophosphamide, *T* paclitaxel, *H* trastuzumab, *P* pertuzumab, *TCH* docetaxel, carboplatin, trastuzumab, *Neg* negative, *Pos* positive, *RS* recurrence score

- An anti HER2 therapy (e.g., trastuzumab with or without pertuzumab) merits to be added to the chemotherapy regimen for patients with human epidermal growth factor receptor 2 (HER2)-positive breast cancer.

Patients either complete entire chemotherapy as NACT or may receive NACT and adjuvant chemotherapy (ACT) both depending upon institutional practice.

According to the CREATE-X trial, women with residual disease following standard NACT may be appropriate candidates for adjuvant capecitabine for triple-negative breast cancer [83].

7.2 Anti-HER2-Targeted Therapy

Patients with malignancies that overexpress HER2 benefit from anti-HER2 therapy. A 2012 meta-analysis of chemotherapy plus trastuzumab versus chemotherapy alone found that adding trastuzumab to ACT improved disease-free survival (DFS) and overall survival (OS) in patients with HER2-positive disease [84].

Women with either node-positive or node-negative high-risk disease (generally defined as tumor size >1 cm were included in the majority of trials demonstrating the efficacy of adjuvant trastuzumab [85].

In a single-arm trial, the benefit of adjuvant trastuzumab plus paclitaxel (anthracycline-free regimen) in patients with low tumor burden HER2-positive tumors was investigated, and 3-year recurrence-free survival rates of around 99% were found [86].

Based on the phase III APHINITY trial, adjuvant pertuzumab for a year may be considered for the high-risk patients with either node-positive disease or node-negative tumors with >2 cm size to improve disease-free survival [87].

Administration of trastuzumab sequentially after completion of all chemotherapy has demonstrated activity but it appears to be less effective than when given concurrently.

We recommend endocrine therapy concurrently with trastuzumab during maintenance treatment (following completion of adjuvant chemotherapy).

The 2012 meta-analysis suggests that trastuzumab should be given for 1 year with adjuvant chemotherapy rather than for shorter periods [84]. Subsequent trials reaffirm this recommendation and also demonstrate no improvement with extension to 2 years [13]. We advocate 1 year of trastuzumab in patients with either node-positive disease or with hormone receptor-negative disease. We suggest a shorter duration of adjuvant trastuzumab (6 months duration) in patients with low risk of disease (defined as node-negative, triple-positive disease) based on a recent meta-analysis done at our center [88].

Patients who received NACT should get trastuzumab in the adjuvant setting to complete a full year of trastuzumab therapy, accounting for the number of cycles of trastuzumab given in both the neoadjuvant and adjuvant settings. Continue pertuzumab with trastuzumab in the adjuvant situation for patients who received neoadjuvant pertuzumab.

7.3 Endocrine Therapy

Patients with malignancies that are hormone receptor-positive (ER, PR, or both) benefit from adjuvant endocrine therapy. The choice of endocrine therapy depends on the menopausal status of the patient. The various endocrine therapies are as follows:

Premenopausal patient

Tamoxifen alone

Tamoxifen with ovarian suppression or ablation—that can be achieved by Surgery (oophorectomy), Pelvic radiation (ovarian ablation), Gonadotropin-releasing hormone (GnRH) agonists.

Tamoxifen—a 2011 EBCTCG meta-analysis compared 5 years of tamoxifen treatment to no endocrine treatment and found a significant reduction in the risk of breast cancer recurrence and mortality at 15 years [89].

Postmenopausal patient—Aromatase inhibitors (AI)—Aromatase is a key enzyme in the conversion of androstenedione to estrogen in peripheral fat tissue and by inhibiting this enzyme. AI block the peripheral conversion of androgen to estrogen. Since this mechanism is predominantly active in postmenopausal woman, AIs are recommended there and not for premenopausal and/or women with chemotherapy-induced amenorrhea. The efficacy among the AIs is comparable [90] and in comparison to tamoxifen, AIs fared better in reducing recurrence risk during therapy and reducing breast cancer mortality both during and after treatment [78].

7.3.1 Premenopausal Women: Choice of Tamoxifen Alone vs. Tamoxifen with OFS

Based on the results of the Suppression of Ovarian Function Trial (SOFT) and the Tamoxifen and Exemestane Trial (TEXT), we recommend Tamoxifen in combination with ovarian function suppression (OFS) rather than tamoxifen alone for women with high-risk breast cancer, inclusive of age ≤35 years, large tumor size, presence of pathologically involved lymph nodes, high tumor grade, lymphovascular invasion and/or high risk of recurrence based on a genomic assay [91].

Tamoxifen is a choice as a single agent to women with low risk of recurrence.

7.3.2 Postmenopausal Women

We perennially use an AI for the postmenopausal breast cancer women in view of superior DFS. However, both agents reduce recurrences and new primary breast cancers and one should be cognizant about the potential toxicities while selecting endocrine therapy.

Adjuvant endocrine therapy is administered for at least 5 years. Unless there is a contraindication to continued endocrine therapy, all patients should receive adjuvant endocrine therapy for at least 5 years (such as prior thrombosis on tamoxifen or osteoporosis refractory to bone-modifying agents). In high-risk women, extended therapy for 10 years is recommended.

8 Metastatic Breast Cancer

In the following circumstances, cytotoxic chemotherapy may be used: (1) hormone receptor-negative breast cancer; (2) hormone receptor-positive breast cancer that has progressed after multiple lines endocrine agents (i.e., endocrine-resistant disease) or has a significant tumor burden including visceral organs.

8.1 Choice of Chemotherapy

Multiple criteria, including tumor burden, ECOG performance status, prior therapies potential toxicities and patient desire, influence the choice of regimen (i.e., single agent or combination) and specific therapy for patients who require chemotherapy. Single-agent chemotherapy is preferred for patients with a small tumor burden. Sequential monotherapy is equally efficacious and less toxic to multiagent therapy and is preferred [92]. A combination regimen is preferred for a small, select subgroup with either frank or imminent visceral crisis; they are usually having a substantial tumor burden (extensive liver metastases or dyspnea related to diffuse lung metastases).

8.2 Duration of Treatment

Duration of chemotherapy should be guided by the patient's performance status, existing and potential toxicities, and access to alternative choices. Patients should continue chemotherapy until they have the optimal response, progressive disease, or unacceptable side effects. There is some evidence to show that extending treatment beyond their best response has benefits. Maintenance treatment was compared to treatment for a predetermined time (range, three to eight cycles) in a meta-analysis of randomized studies [93]. Progression-free survival (HR 0.64, 95% CI 0.55–0.76) and overall survival improved (HR 0.91, 95% CI 0.84–0.99) with longer treatment duration of paclitaxel and gemcitabine in a randomized trial [94].

9 HER2-Positive MBC

9.1 First-Line Therapy

9.1.1 Trastuzumab

Slamon et al. [95] provided the first definitive evidence of anti-HER2-targeted therapy in a clinical trial where in treatment naïve metastatic hER-2-positive patients were administered chemotherapy with or without trastuzumab. The combination of chemotherapy and trastuzumab resulted in a significantly superior outcomes including higher objective response rate, longer time to progression (TTP; 7.4 vs. 4.6 months; $p<0.001$) and enhanced overall survival (OS; 25 vs. 20 months; $p = 0.01$).

9.1.2 Lapatinib

Chemotherapy with or without lapatinib was tested in a randomized trial, wherein OS was 20.7 months in the combination arm versus 20.5 months in the chemotherapy alone arm [96]. Lapatinib and trastuzumab with taxane were examined in the MA.31 study, and PFS was observed to be poorer with lapatinib (8.8 months vs. 11.4 months with trastuzumab) at the interim analysis [97]. At present, based on the foregoing findings, trastuzumab-based regimens are the standard of care in first-line situations.

9.1.3 Trastuzumab Plus Pertuzumab

The Cleopatra trial [98] investigated adding pertuzumab to standard taxane and trastuzumab therapy and demonstrated superiority of pertuzumab with respect to OS (56.5 months in pertuzumab arm vs. 40.8 months with placebo) at a median follow-up of 50 months.

9.2 Second-Line Therapy

There is phase III randomized evidence to continue anti-HER2 therapy in patients whose disease has progressed on first-line trastuzumab-based therapy with alternating chemotherapy regimen. Treatment options include changing to the antibody drug conjugate T-DM1, adding the mTOR pathway inhibitor everolimus, changing to a Capecitabine plus lapatinib regimen.

10 Hormone Receptor-Positive Metastatic Breast Cancer

Endocrine therapy (ET) is preferred option unless there is clinically severe disease that requires a faster response or endocrine resistance. There are various determinants including menopausal status, comorbidities and drugs given in the adjuvant setting in deciding which endocrine agent to use. The sequential use of endocrine therapy—tamoxifen, Aromatase inhibitors and Fulvestrant—has been the main stay of treatment since years. In last few years, introduction of newer targeted therapies (like CDK4/6 inhibitors, PI3K inhibitors) have provided non-chemotherapy-based options which have improved the outcome of hormone receptor-positive metastatic breast cancer patients. The effectiveness of CDK4/6 inhibitors in combination with endocrine therapy has been confirmed in multiple phase III studies and is now the preferred first-line treatment [99–101]. Around 40% of patients have activating mutations in PI3KCA, and use of alpelisib along with fulvestrant in these patients has shown improved PFS compared to hormonal therapy alone [102].

11 Special Scenarios

11.1 Young Women with Breast Cancer

Recent data from Tata Memorial Centre in large cohorts of young breast cancers (YBC) defined as ≤40 years of age (*N* = 1228) suggest that they represent higher percentage of total BC (16.7%) then in the west. Furthermore, in this study Bajpai et al. [103] demonstrated that a large majority are diagnosed at an advanced stage due to multitude of reasons including delayed diagnosis and/or referral. They are of higher stage, grade, node positives and predominantly TNBC and HER2 positives. There were unique concerns regarding significant postmenopausal symptoms post treatment and concerns regarding fertility preservation. A small fraction of YBC could conceive and successfully deliver live babies post successful treatment of breast cancer.

YBC women have challenges associated with body image, including chemotherapy induced alopecia which can be circumvented via scalp cooling devices. A randomized controlled trial by Bajpai et al. [104] has shown success with regard to alopecia prevention as well as hair regrowth. Yet another study from the institute by Bajpai et al. showed in a large cohort of nonmetastatic TNBC that they present in an advanced stage and had aggressive clinicopathological features which adversely affects outcomes. Pregnancy associated breast cancer (PABC) is a unique entity and encompasses two entities breast cancer diagnosed during pregnancy (BCP) or 1-year postpartum (BCPP). Bajpai et al. [105] in the first Indian PABC registry demonstrated the prevalent delayed diagnosis and again aggressive clinicopathological features including TNBC and higher grades and stage. Stage and biology matched outcomes of PABC were comparable to non-PABC and those of YBC and TNBC with published literature.

11.2 Palpable DCIS (pDCIS)

pDCIS has a 10% to 14% risk of harboring an invasive component. It is essential to differentiate microinvasive DCIS from multiple foci of invasive ductal carcinoma (IDC) [106] in a background of DCIS with extensive intraductal component (EIC). The pathologist's role is critical in defining the same.

The incidence of axillary lymph node metastases with DCIS is only 1.4%, while with DCIS-M, it is higher at 5.1% [107]. Possible indications for axillary lymph node dissection are the suspicion of microinvasion, such as the presence of a clinically palpable node or palpable comedo-type DCIS. Due to the underestimation of invasion in biopsies of pDCIS, lymphatic mapping using sentinel lymph node biopsy or axillary sampling at the time of surgery, with both modified radical mastectomy and breast-conserving procedure may be considered [108]. The role of adjuvant therapy in pDCIS and DCIS-M is still not clear.

1 Introduction

Lung cancer is the most frequently diagnosed cancer worldwide and is a major health problem in both developed and developing countries in the world. Lung cancer is the most common cause of death in both men and women. Survival is generally poor with only less than 10% of patients remaining alive at 5 years after diagnosis [1]. Smoking is the main risk factor for lung cancer in developed countries, accounting for 80–90% of cases. About 10–15% of cases occur in non-smokers, and these may often be caused by a combination of genetic factors and exposure to environmental hazards like radon gas, asbestos, second-hand smoke, or other forms of air pollution [2–4].

Lung cancer is divided into two main types: non-small cell lung cancer (NSCLC) and small cell lung cancer (SCLC). Although the etio-pathogenesis is similar, treatment principles are different for each of these types. NSCLC is a heterogeneous aggregate of different histologies. The most common histologies are squamous cell carcinoma, adenocarcinoma, and large-cell carcinoma. These histologies are often classified together because approaches to diagnosis, staging, prognosis, and treatment are similar. Generally, treatment involves a multidisciplinary approach with surgery, systemic therapy, and radiation therapy used in various combinations.

2 Incidence and Epidemiology

Lung cancer occurred in approximately 1.8 million patients worldwide in 2012 and caused an estimated 1.6 million deaths. Lung cancer is known to account for more deaths than any other type of cancer.

In India, as per GLOBOCAN 2012 report, the estimated incidence of lung cancer was more than 70,000 cases across all ages and sexes; the age-standardized rate (ASR) per 100,000 was 6.9, with a cumulative risk of 0.85. Incidence of lung cancer ranked fourth overall among the various types of cancer behind breast, cervical and oral cavity cancer, ranking

second in males and seventh in females. In Indian males, lung cancer had a crude incidence rate of 8.3, ASR of 11 and cumulative risk of 1.36; in Indian females, crude incidence rate was 2.7, ASR 3.1 and cumulative risk 0.37. Lung cancer was the third most common cause of cancer-related deaths in India after breast and cervical cancer. Among Indian males, lung cancer was the leading cause of cancer mortality and among Indian females seventh after breast, cervix, colorectal, ovary, stomach and oral cavity cancers. It is also estimated that by 2025, the incidence of lung cancer would increase to more than 1 lakh and the mortality to 92,601. It is expected that lung cancer will remain a major health problem at least for the next three to four decades, even if smoking cessation interventions lead to a reduction in incidence [5–8].

Tobacco smoking remains the single most important risk factor (80–90%) for lung cancer with a smaller proportion (10–20%) attributable to occupational exposure to various carcinogenic agents. Comparatively, the smoker-non-smoker ratios have been low in Indian studies compared to those from the West. The percentage of tobacco-related products smoked in India are beedis (28.4–79%), cigarettes (9.0–53.7), hookah (3.4–77.3) and mixed (7.5–13.6). The relative risk of developing lung cancer varies according to the type of tobacco smoking; 2.64 for beedi smokers, 2.23 for cigarette smokers and 2.45 as the overall risk for smoking tobacco. Passive, second-hand smoking and environmental tobacco smoke are also known lung carcinogens. The risk also increases with an increase in the number of smokers in the house and the duration of exposure. Childhood exposure to environmental tobacco smoke is strongly associated with the risk of developing lung cancer [9, 10].

In the Western countries and most of the Asian countries, adenocarcinoma has surpassed squamous cell carcinoma as the leading histologic variant of lung cancer. This shift can be partly attributed to the changing smoking pattern and increasing incidence of lung cancer in women and non-smokers. However, most of the older and some recent Indian series report that squamous cell carcinoma continues to be the most common histology. However, single-center-based reporting from the established tertiary cancer centers point toward adenocarcinoma being the most common NSCLC subtype.

Occupational exposure leading to lung cancer is definitely linked with workers exposed to asbestos, arsenic, nickel, chromium, beryllium, silica, chloro-methyl ether, mustard gas and radiation from uranium, radon; while agents like acrylonitrile, cadmium, formaldehyde and vinyl chloride are suspected to be carcinogenic [11].

There is a genetic component in the carcinogenesis of lung cancer both with regard to host susceptibility, with or without exposure to tobacco smoke to the development of malignancy and to an individual's responsiveness to biologic therapies. Polymorphisms in genes associated with DNA repair enzymes active in base excision repair (XRCC1 and OGG1), nucleotide excision repair (ERCC1, XPD, and XPA) and double strand break repair (XRCC3), and different mismatch repair pathways have been linked to lung cancer risk. Several of these cancer susceptibility genes have been associated with increased levels of DNA adducts; additionally acquired or epigenetic changes in DNA chromosome like DNA methylation, histone de-acetylation and phosphorylation can also lead to increased lung cancer risk [12]. Despite many genetic association studies, the role of specific genes in increased risk for lung cancer remain poorly understood.

The high morbidity, mortality associated with NSCLC, and relative high prevalence in high-risk population make it an appropriate disease for screening. Since mortality and survival are related to the stage at diagnosis, early detection may be beneficial. Many randomized controlled trials in the western world have shown reduced lung cancer specific and all-cause mortality by screening with low-dose CT scan LDCT in patients with personal smoking exposure. According to the U.S. Preventive Services Task Force, annual screening for lung cancer with low-dose CT is recommended in adults aged 55–80 years who have a 30 pack-year smoking history and currently smoke or have quit within the past 15 years [13, 14]. However, the enormous financial burden of the screening programmes in existing health-care system and lack of uniform accessibility to diagnostic modalities are major road blocks for implementing a successful screening programme in India [15].

3 Clinical Presentation

Initial clinical presentation in lung cancer could be a manifestation of the local disease, loco regional spread, extra thoracic spread (distant metastases) or due to paraneoplastic syndrome. Cough occurs in 70–90% of patients with lung cancer and may be produced either by small tumour interfering with bronchial peristalsis or by ulceration of bronchial mucosa. Cough and sputum production may be nonspecific, as cigarette smoking also produces bronchorrhea and excessive mucus. Peripheral tumours may also attain large size without producing cough. Severe bouts of cough can also result in pneumothorax due to rupture of an emphysematous bleb, fainting (cough syncope) or even rib fracture.

Hemoptysis is a common symptom occurring in 25–40% of patients. It may be due to ulceration of the bronchial mucosa by tumour or related to rupture of bronchial veins or venules leading to significant loss of blood. Breathlessness is also an early symptom occurring in about 60% of patients. It may be disproportionate to radiological findings due to associated underlying smoke-related lung changes. Wheezing, stridor or sudden increase in breathlessness is highly suggestive of a partial bronchial obstruction and may result from pressure and narrowing of large bronchus or trachea.

Chest pain is also a common symptom in lung cancer and may be present without frank evidence of invasion of the pleura, chest wall or mediastinum. Since lung parenchyma lacks pain fibres, the origin of this type of pain is sometimes vague. Pleural metastasis may result in severe chest pain necessitating narcotics. Persistent chest pain with invasion of bony thorax is often caused by squamous cell carcinoma. Superior sulcus tumour often produces shoulder and arm pain because of invasion of brachial plexus (Pancoast syndrome). It can be accompanied by Horner's syndrome, brachial plexopathy and reflex sympathetic dystrophy.

Hoarseness of voice in association with lung cancer is caused by involvement of the recurrent laryngeal nerve. The phrenic nerve can be invaded by the primary tumour or bulky adenopathy. The left recurrent laryngeal and phrenic nerve are more commonly affected than the right. Dysphagia can result from oesophageal obstruction by bulky mediastinal adenopathy or recurrent laryngeal nerve injury. Superior vena cava syndrome is a common complication of lung cancer and a consequence of obstruction of superior vena cava by right upper lobe or hilar tumour. The syndrome is characterized by facial swelling, flushing, and neck and chest wall vein distention.

Approximately 15–20% of lung cancer patients present with pleural effusion. Pericardial effusion develops in 5–10% of patients and typically occurs in the setting of progressive locally advanced disease [16, 17].

Patients with advanced disease can present with symptoms specific to site of distant metastases. Most common sites of metastases include brain, bone, adrenals and liver. The manifestations of brain metastasis are variable and depend on the location of the lesion and the amount of the associated oedema or haemorrhage. Patient may present with focal weakness, generalized or focal seizures, confusion or dementia, dysphasia, visual disturbances, or ataxia. Leptomeningeal disease may present as cranial nerve palsies or cauda equine syndrome. Bone is a commonly involved site of metastases; patient may present with significant bone pain requiring narcotics or neurological deficits secondary to compression syndromes.

Patients with paraneoplastic syndromes, secondary to systemic manifestations of lung cancer, could present with endocrinological, neurologic, musculoskeletal, haematological or dermatological abnormalities.

In around 5% of patients, lung cancer may be discovered incidentally during the investigation of an unrelated complaint, or on a chest radiograph done as part of a pre-operative evaluation or as part of an extended physical examination [16].

4 Evaluation and Work-Up

Given the importance of staging in decision-making process, a thorough staging workup for NSCLC should be carried out to evaluate the extent of disease. A complete metastatic workup is indicated in all patients with potentially operable NSCLC and in those who can be offered radical therapy such as concurrent chemo radiation with a curative intent. Pre-treatment workup includes:

1. Chest X-ray
2. CT scan chest and upper abdomen
3. Fibre optic bronchoscopy
4. Cytology/histological diagnosis—sputum cytology, broncho-alveolar lavage/brushings cytology, post bronchoscopy sputum cytology, CT-guided biopsy
5. Pulmonary function test and diffusion coefficient of carbon monoxide (DLCO)
6. Ventilation-perfusion (V/Q) scan—if pulmonary function tests reveal borderline pulmonary reserve
7. Resting 2D ECHO/Stress 2D ECHO may be performed to assess cardiac status in patients planned for major resections or have pre-existing cardiac co-morbidity
8. Invasive mediastinal staging is indicated in all patients with potentially operable NSCLC. Peripherally located T1a squamous cancers with negative mediastinal imaging on PET-CECT may be excluded. If available, combined EUS/EBUS with guided FNAC is the preferred initial staging modality. All negative EBUS studies should be confirmed by video-assisted mediastinoscopy (VAM)
9. Metastatic workup—PET-CT scan, MRI brain—indicated in all patients with non-metastatic NSCLC fit for radical treatment. Patients with T1 (T <10 mm), N0 NSCLC with no symptoms of metastatic disease do not require a routine metastatic workup.

Histopathological diagnosis of NSCLC includes squamous cell carcinoma (25–30%), adenocarcinoma (35–40%) and large cell carcinoma (10–15%). Various IHC markers may aid in differentiation between the types (Table 1).

Table 1 NSCLC histopathology

Histology	IHC markers
Squamous cell carcinoma	Cytokeratin (CK) cocktail—AE1/AE3 CK5/6 CK7 (rare)
Adenocarcinoma	Cytokeratin cocktail—AE1/AE3 CK7, TTF-1 Neuroendocrine markers—CD56, NSE (rare)
Large-cell carcinoma	Cytokeratin, TTF-1 rare Neuroendocrine markers—CD56, NSE (rare)

Cervical mediastinoscopy remains the gold standard for staging the mediastinum and should be done in all patients planned for surgical excision. Endoscopic ultrasound (EUS) and endobronchial ultrasound (EBUS) guided fine needle aspiration cytology can be used for initial staging where the expertise is available, but in case of negative staging, invasive staging with mediastinoscopy is required.

Pre-operative pulmonary evaluation tests are done to assess adequacy of pulmonary reserve prior to definitive treatment including lung surgery or chemoradiation. This includes spirometer, 6-min walk test, shuttle test and other cardio-pulmonary exercise testing.

Pre-treatment identification and treatment of concomitant risk factors are also vital. This may include management of smoking cessation, co-existing pulmonary disease with bronchodilators, intermittent positive pressure breathing (IPPB), chest physiotherapy and antibiotics (if presence of infection is suspected).

The eighth edition of the American Joint Commission on Cancer (AJCC) TNM staging system for non–small cell lung cancer [18] was introduced in January 2017 and implemented from January 2018 Staging can be found in AJCC Cancer Staging Manual, Eighth Edition, Page no. 447–448, Chapter no. 36, Lung, Table: Definition of TNM and AJCC prognostic stage groups which can be accessed at https://emedicine.medscape.com/article/2007813-overview.

The eighth edition of the TNM staging system is based on the recommendations of the International Association for the Study of Lung Cancer (IASLC) Staging and Prognostic Factors Committee (SPFC) [19]. The main purpose of stage classification is to provide a uniform nomenclature about the anatomic extent of disease that can be used consistently globally.

4.1 Predictive and Prognostic Biomarkers

Several predictive and prognostic biomarkers have emerged for NSCLC. Key established predictive biomarkers include sensitizing EGFR mutations, ALK rearrangements, ROS1 rearrangements, BRAF V600E point mutations and PD-L1 expression levels. Emerging biomarkers include HER2 mutations, RET rearrangements, MET amplification and MET exon 14 skipping mutations [20].

In all NSCLC patients with an element of adenocarcinoma, regardless of the clinical profile, genomic testing for EGFR and ALK alterations as a part of the standard diagnostic evaluation is recommended. . The National Comprehensive Cancer Network (NCCN) extends the recommendations for metastatic NSCLC to include BRAF, ERBB2 (HER2), MET, RET and ROS1 [21].

Epidermal growth factor receptor is a cell signalling, transmembrane protein intimately involved in proliferation. Mutations can occur in the kinase region leading to unregulated phosphorylation and activation of cell survival/proliferation pathways. The incidence of EGFR mutation is the highest in non-smokers, female gender with adenocarcinoma. Of all the various EGFR gene known mutations in lung adenocarcinoma, 90% are of exon 19 and L858R point mutation in exon 21. These mutations are more frequent in Asian populations with its frequency reaching 60% as compared to 10% in US populations [22–25].

The echinoderm microtubule associated protein-like 4 (EML)-anaplastic lymphoma kinase (EML4-ALK) protein results from the fusion of PTK EML-4 with ALK, a transmembrane tyrosine kinase. The resulting constitutive oligomerization leads to persistent mitogenic signalling and malignant transformation. ALK mutation is reported in approximately 3–7% of lung cancers, seen more frequently in young, non-smoking adults with adenocarcinoma histology. In the majority of patients, ALK rearrangements are exclusive and do not overlap with other oncogenic mutations [26–28]. ROS1 gene promotes proliferation and inhibits apoptosis; mutations are seen in 1–2% of all NSCLC patients through a rearrangement that leads to unregulated production of fusion proteins which retain the kinase domain.

5 Principles of Management (An Integrated Brief Overview of RX Philosophy)

All patients should be preferably discussed in a multidisciplinary tumour board meeting including specialists from surgical oncology, radiation oncology, medical oncology, radiology, bio-imaging, pulmonologist and palliative care departments. Ancillary support care may be provided by psychiatrists, occupational and physiotherapists.

Treatment for NSCLC is planned according to the clinico-radiological stage, cardio-pulmonary reserve and performance status. Patients should be treated in concordance with standard consensus guidelines, including institutional evidence-based medicine.

5.1 Localized (T1-3, N0-1) Non-Small Cell Lung Cancer (NSCLC)

Surgical resection is the cornerstone in the treatment of early-stage NSCLC. Invasive mediastinal staging should be performed on all patients planned for surgical excision. Lobectomy or pneumonectomy along with N1 and N2 lymph nodal resection and mapping (sampling or systematic lymph node dissection) is done depending on the extent of disease (provided the patient has adequate pulmonary reserve). Limited resections (segmentectomy, wedge resection) may be done only if pulmonary reserve is inadequate for lobectomy, provided otherwise medically fit for surgery. Curative SBRT or radical radiotherapy may be administered if the patient is medically unfit for surgery. All resected NSCLC (T size >4 cm) or any node positive (N1 or more) receive adjuvant cisplatin-based chemotherapy. Postoperative radiation may be indicated in the presence of positive margins, pathological N2 disease or residual disease. Patients with pre-operative diagnosis of N2 disease undergo neoadjuvant chemotherapy followed by surgery. Patients progressing on neoadjuvant chemotherapy are treated with definitive chemoradiotherapy.

5.2 Loco-Regionally Advanced (T4 and N3) NSCLC

Patients with unresectable NSCLC in good general condition are managed with combined chemoradiotherapy. Patients who may not tolerate combination therapy are treated with radiotherapy alone.

Patients with metastatic lung cancer are treated with systemic therapy, which may include chemotherapy, targeted therapy or immunotherapy. Symptomatic bone, brain and soft tissue metastases may be palliated with radiation therapy. Patients in poor general who are unfit for any form of tumour-directed therapy are given best supportive care.

6 Surgical Management

6.1 Early-Stage NSCLC

Early-stage NSCLC (stage I and stage II) are generally treated with surgery as the initial modality. Resection of the primary tumour and evaluation of draining lymph nodes in the ipsilateral hilum and mediastinum are key aspects in surgery for early-stage NSCLC.

6.1.1 Primary Tumour Resection

Lobectomy is the current standard for resection in lung cancer. If the patient has adequate pulmonary reserve, lobectomy, bi-lobectomy or pneumonectomy should be done depending on the extent of disease. The large scale, ACOSOG Z0030 (ALLIANCE) trial, set the benchmark for surgical outcomes in early-stage NSCLC; with a median follow-up of 6.7 years, overall survival at 5 years was 72% for T1 tumours and 55% for T2 tumours [29]. Lung resections carry significant morbidity with up to 37% of patients experiencing minor or major postoperative morbidities. Minor complications are more common (atrial arrhythmia and prolonged air leak) while major complications like respiratory failure can occur in patients with poor baseline pulmonary function. The operative mortality following lobectomy is reported to be 1–3% in high volume surgical centres.

Video-assisted thoracoscopic surgery (VATS), typically involves two to four port sites and a 5–8 cm access incision. It involves removal of lung lobe containing the tumour with ligation of each of the broncho-vascular structures and removal of hilar and mediastinal lymph nodes. VATS differs from mini-thoracotomy by the lack of rib spreading and complete thoracoscopic visualization. In a propensity score matched analysis, no difference was observed in overall survival, disease-free survival and freedom from development of a new primary tumour between the two approaches [30]. However, most large series of VATS lobectomy report a similar pattern of perioperative complications but at significantly reduced rates as compared to the open approach. Another modern technological advancement, robotic lobectomy has multiple advantages including reduced pain at port site, and binocular visualization. Large, prospective studies with robust long-term oncologic outcomes are lacking; however, initial reports show comparable survival outcomes between the VATS and robotic approaches.

Sub-lobar resection refers to removal of less than a pulmonary lobe. Limited resection (segmentectomy, wedge resection) may be done only if pulmonary reserve is inadequate for lobectomy, provided otherwise medically fit for surgery. However, a randomized trial (LCSG) [31] and few other nonrandomized trials have demonstrated increased local recurrences and lower survivals with sub-lobar resections compared to lobectomy [32].

6.2 Nodal Evaluation and Resection

Evaluation of the draining lymph nodes provides valuable staging information and is an integral part of surgery for NSCLC. It can be done either pre-operatively or peroperatively. Endobronchial ultrasound and **c**ervical mediastinoscopy are pre-operative procedures for evaluating mediastinal lymph nodes for cancer involvement. Peroperatively, a systematic mediastinal lymph node sampling (SMLND) may be performed, where lymph nodes at each of the ipsilateral mediastinal station are biopsied (stations 2R, 4R, 7 and 9R on the right side and levels 5, 6, 7 and 9 L on the left), or by formal mediastinal lymphadenectomy wherein all nodes and soft tissue between anatomical landmarks are dissected.

Although the ACOSOG Z0030 trial did not demonstrate a benefit in overall survival with SMLND over sampling alone in node negative patients [29], an identical large randomized trial from China demonstrated a significant survival benefit with SMLND in operable NSCLC. Pooled analysis of four RCTs shows a trend toward improved survival with SMLND and none of these trials demonstrate any additional morbidity or mortality with SMLND [33].

6.3 Locally Advanced NSCLC (T1–3, N2)

Stage III NSCLC represents a heterogeneous group of malignancies with locoregional involvement by extension of the primary tumour and/or ipsilateral lymph node involvement. Stage IIIB/IIIC with N3 disease (supraclavicular and/or contralateral mediastinal lymph nodes) is not typically treated surgically. Surgical indications have not been definitely established for stage IIIA and are treated with a multimodality approach. The use of surgery in these treatment regimens is not universally accepted and should be tailored to individual case. Stage IIIA NSCLC patients fall into two classes: pre-operatively diagnosed N2 disease and surgically discovered N2 disease.

6.3.1 Pre-Operatively Diagnosed N2 Disease

Patients with clinico-radiological N2 disease should undergo mediastinoscopy for histological confirmation of N2 status. Outcomes in these patients with surgery as a sole treatment modality have been historically poor, with studies showing 5-year survival rates less than 10%. Therefore treatment strategies have evolved to include multimodality approaches. A large meta-analysis showed significant benefit to postoperative chemotherapy in this subset; however, there was a significant incidence of grade 3 or 4 toxicity events, and 33% of them could not complete the planned adjuvant therapy [34, 35].

Several studies have evaluated the impact of neoadjuvant chemo-irradiation, followed by surgery. In the Intergroup (INT) 0139, patients were treated with induction chemo-irradiation and then randomized between surgery or further radiotherapy [36]. In the ESPATUE phase III trial, patients received induction chemotherapy followed by chemo-irradiation and then surgery [37]. In the EORTC 08941 trial, patients responding to induction chemotherapy were randomized to surgery or radiotherapy [38]. All three trials showed that overall survival was not different between surgical and non-surgical arms, although progression-free survival was improved in the surgical group in the Intergroup trial. Also, mortality of patients undergoing complex, intra-pericardial pneumonectomies was unacceptably high. An unplanned sub-analysis showed significant survival difference in patients undergoing lobectomy after induction chemo-irradiation compared to a similar group treated by chemo-irradiation only. A recent meta-analysis including randomized trials comparing surgery with definitive radiation therapy demonstrated no difference in overall and progression-free survival between surgery and radiotherapy in the setting of stage III NSCLC [39]. Patients who progress on neoadjuvant chemotherapy are treated with definitive chemoradiotherapy. Since mediastinal nodal down-staging is an important prognostic factor, a thorough attempt to restage the mediastinum after induction therapy should be undertaken before embarking on any major surgical intervention.

6.3.2 Surgically Discovered N2 Disease

Patients who have not received pre-operative chemotherapy should be given postoperative chemotherapy (see below). The role of adjuvant radiotherapy in completely resected N2 NSCLC is debatable (see below). Subset analysis in the PORT meta-analysis showed no difference in survival [40]; however, a large SEER database analysis showed improvement in survival with postoperative radiation in patients with N2 disease [41].

7 Radiation Management

Radiotherapy (RT) is an essential modality in the management of NSCLC. RT is the primary treatment modality for locally advanced, unresectable disease and is usually delivered concurrently with chemotherapy. In postoperative setting, RT can used as an adjuvant treatment to improve locoregional control. Radiotherapy is also frequently used for the palliation of symptoms in advanced and metastatic lung cancer. RT for NSCLC is usually delivered using external-beam radiotherapy via a linear accelerator. Newer techniques, such as intensity modulated (IMRT) and image-guided radiation therapy (IGRT), have improved the therapeutic ration by reducing the toxicity profile and allowing for dose escalation.

7.1 Early-Stage NSCLC

Surgical resection is currently the standard treatment for the medically operable ES-NSCLC, with 10-year survival rates ranging from 45% to 75% [42]. However, about 20% of the patients with stage I NSCLC cannot or do not undergo surgery owing to poor pulmonary, cardiac function and perceived higher risk of mortality with surgery, especially in elderly patients [43]. Stereotactic body radiotherapy (SBRT), also known as stereotactic ablative radiation therapy (SABR), typically involves the delivery of 1 or a few large-dose fractions of 8–30 Gy per fraction. Technological advances in image guidance and radiation treatment delivery techniques have enabled the delivery of high doses to targets with tighter margins and high gradients outside the target, thereby minimizing doses to surrounding normal tissues. SBRT utilizes smaller margins for set-up uncertainty, aided by 4-dimensional computed tomography (4DCT), multiple conformal or intensity modulated beams or arcs and volumetric image guidance.

Several long-term retrospective series, phase II and III studies have evaluated SBRT in medically inoperable ES-NSCLC and shown 5-year local control rates ranging between 73% and 92% and overall survival (OS) of 50–70% [44–46]. Various total dose and fractionation schedules have been utilized in the past; the overall dose delivered to the tumour is strongly associated with local control. In a retrospective review, Onishi et al. analysed a variety of dose fractionation schedules and showed that local control and survival were significantly improved with BED_{10Gy} greater than 100 Gy, with 5-year local recurrence rate of 8% for $BED_{10Gy} > 100Gy$ versus 26.4% for $BED_{10Gy} < 100Gy$ ($p < 0.001$) [47].

Dose fractionation is also determined based on the location of the primary disease. In patients with central tumours undergoing SBRT, a pivotal phase II study reported that a dose of 60–66 Gy in 3 fractions was associated with excessive toxicity and treatment-related death. However, severe toxicity has not been noted when a "risk-adapted" dosing strategies were used [48, 49]. Studies have also shown the safety of SBRT in elderly patients. SBRT also appears to be well-tolerated in patients with severe COPD, with grade 3–4 toxicities occurring in <10% of patients [50].

There is also an ongoing debate about the role of SBRT in medically fit and operable patients. Two ambitious randomized trials, set to address this debate, closed prematurely due to slow accrual. A pooled analysis of both these two trials in operable patients showed a 16% higher 3-year survival with SBRT compared to surgery, due to a higher rate of perioperative mortality in the surgical group [51]. A propensity score matched analysis showed that rates of treatment-associated mortality and severe toxicity were lower with SBRT compared with VATS lobectomy [52]. Data from many other retrospective and prospective phase II studies of SBRT compared to surgery have shown equivocal survival outcomes. The importance of shared decision-making between oncologists and patients cannot be overemphasized in arriving at an optimal management plan based on a patient's preferences and values. The role of SBRT in operable patients continues to be studied in many ongoing studies (VALOR study, SABRTooth and STABLE-MATES).

7.2 Locally Advanced, Non-metastatic NSCLC

RT is the cornerstone in the definitive treatment of unresectable, locally advanced, non-metastatic NSCLC either alone or given concurrently or sequentially with systemic therapy. The seminal study by Perez et al. in 1980 compared different fractionation RT schedules and established the standard radiation dose of 60 Gy in 30 fractions in NSCLC [53]. Subsequent studies have tried to escalate to higher dose to target and utilized altered fractionation to improve the therapeutic ratio [54]. Although few of them did demonstrate improved local control and survival, there has also been a concomitant increase in treatment-related toxicity.

Combined modality treatment with chemotherapy was explored earliest in the CALGB 8433 trial and RTOG 8808 trial, both of which compared sequential chemotherapy followed by RT and RT alone [55, 56]. Two-year survival rates were significantly better with combined treatment in both the trials. A meta-analysis of 22 trials demonstrated significant overall benefit with chemotherapy, resulting in an absolute benefit of 3% at 2 years and 2% at 5 years [57]. Comparison between concurrent and sequential chemotherapy with radiation has shown significant benefit of concurrent schedule on overall survival (HR, 0.84; 95% CI, 0.74 to 0.95; $p = 0.004$), with an absolute benefit of 5.7% at 3 years and 4.5% at 5 years [58]. Addition of chemotherapy to hyper-fractionated RT has shown similar survival improvement but at the cost of additional grade 3 haematological and non-haematological toxicity [59].

In the CALGB 39081 phase 3 study, patients received definitive chemoradiation following induction chemotherapy versus immediate concurrent chemoradiation therapy alone for LA NSCLC [60]. This study showed that induction chemotherapy was associated with increased toxicity, but no observable survival advantage, reduction in distant metastasis or decrease in locoregional progression. Currently, there is no randomized data specifically supporting the role for consolidation chemotherapy after chemoradiation therapy for the improvement of overall survival; however, this treatment is still routinely given to address micro-metastatic disease particularly, especially if full systemic chemotherapy doses were not delivered during radiation therapy [61]. Use of targeted therapy (TKI and monoclonal antibody) concurrently with radiation has not been proven beneficial till date. Earlier studies showed increased incidence of radiation pneumonitis when erlotinib was utilized with RT [62, 63].

The advent of modern radiation techniques has prompted widespread use of three-dimensional conformal RT (3DCRT), IMRT and IGRT in treatment of NSCLC. Earlier studies established the dosimetric advantage of IMRT over 3DCRT in terms of significant reduction in doses to lung, heart and oesophagus. Many clinical studies have also shown very low incidence of grade 3 or more esophagitis and pneumonitis with IMRT [64]. However, attempts to escalate total dose in modern era have yielded mixed clinical results and need to be further studied [65].

Next generation treatment planning currently being clinically investigated in the treatment of NSCLC includes use of proton therapy, heavy ion therapy, 4π treatment planning systems and combination of RT with novel immunotherapy agents.

7.3 Postoperative RT (PORT)

PORT Meta-analysis Trialists Group collated data from 9 trials and reported a detrimental effect of PORT in patients with stage I/II and N0/1 disease [40, 66]. Many of the studies trials used older conventional RT techniques, and this might have masked a true benefit of PORT. Positive margins and gross residual disease are indications for PORT; the role of PORT in patients with completely resected N2 disease remains debatable. Some recent retrospective studies have suggested a survival benefit with PORT for pN2 disease [41]. With the use of PET-CT scans and endoscopic staging, preoperative mediastinal lymph node staging has improved vastly in the past decade, and incidentally detected pN2 disease has become a less common scenario. Recently, the LungArt trial and PORT-C trial have demonstrated no survival benefit with the addition of PORT in pN2 disease.

7.4 Palliative RT

A majority of patients with NSCLC are diagnosed with locally advanced (stage III) or metastatic (stage IV) disease who receive palliative intent radiation therapy, where the primary goal is to improve quality of life by reducing pain and other symptoms. Palliative radiation therapy can alleviate many symptoms of lung cancer including pain, cough, dyspnoea and haemoptysis. It has also been shown to improve overall quality of life in symptomatic patients [67]. In patients with stage III NSCLC unsuitable for curative therapy but who have a good performance status are candidates for systemic therapy and have a life expectancy of 3 months or more, administration of a platinum containing chemotherapy doublet concurrently with moderately hypo-fractionated palliative thoracic radiation therapy has been recommended over treatment with either modality alone.

8 Medical Management

Few of the important landmark studies pertaining to systemic therapy in NSCLC are listed in Table 2.

8.1 Early Stage

Adjuvant systemic therapy has a vital role in patients who undergo surgical resection for stage I lung cancer, especially in a subset of patients with stage IB disease who are at high risk for disease recurrence. These high-risk features include primary tumour size >4 cm, poorly differentiated histology, lympho-vascular invasion or inadequate/unknown lymph node sampling. Additionally, adjuvant systemic chemotherapy is indicated in all completely resected NSCLC patients with any node positive (N1 or more). The most commonly used adjuvant chemotherapy regimens are cisplatinum in combination with vinorelbine or etoposide. Many large multicentre randomized controlled trials and meta-analyses have shown that cisplatin-based adjuvant chemotherapy in completely resected NSCLC is associated with a significant survival advantage [34, 35, 68].

8.2 Locally Advanced

Neoadjuvant chemotherapy (NACT) followed by surgery is an option in resectable NSCLC patients with bulky or multistation mediastinal nodes. Data from 15 randomized studies showed that NACT significantly improved R0 resection rates, overall survival, time to distant recurrence, and recurrence-free survival in resectable NSCLC [69]. A phase III study comparing pre-versus postoperative chemotherapy found no difference in survival, but a larger proportion of patients completed treatment in the NACT arm [70]. However, adjuvant chemotherapy allows for more reliable pathological staging to establish if subsequent chemotherapy is appropriate.

Evidence from a meta-analysis and 12 randomized controlled trials have shown survival benefit with cisplatin-based chemotherapy and radical radiotherapy compared to radiotherapy alone [71, 72]. Data from 7 randomized trials showed that concomitant chemoradiotherapy improved survival compared with sequential chemoradiotherapy, albeit at the cost of additional toxicity, especially esophagitis [58].

8.3 Metastatic NSCLC

In the past few decades, several randomized clinical trials have investigated the effect of systemic chemotherapy in patients with metastatic NSCLC. An individual patient data meta-analysis showed that cisplatin-based chemotherapy is associated with an absolute increase in one-year survival of 5–10% in patients with metastatic disease and increased median overall survival [73]. Few other meta-analyses on published literaturea have also showed that systemic chemotherapy prolongs survival compared with best supportive care alone [57, 74].

Although platinum-based regimens have significantly higher hematologic toxicity, nephrotoxicity, and nausea and vomiting, they are considered the standard first-line treatment in advanced NSCLC. A phase III trial showed superior overall survival for cisplatin and pemetrexed combination compared to cisplatin and gemcitabine in

Table 2 Key systemic therapy studies in NSCLC

Study	Arms	OS in Months (HR)	PFS in months (HR)
Initial therapy			
Chemotherapy			
Non-squamous—multiple RCT	Platinum doublet—gemcitabine/paclitaxe/ pemetrexed	12 months—40%	4
Squamous—Multiple RCT	Doublet—paclitaxel/docetaxel/gemcitabine	12 months—35%	4
Immunotherapy			
Keynote 024 (PD L1 > 50%)	Pembrolizumab v/s chemotherapy	6 months (80.2 v/s 72.4) (0.60)	10.3 v/s 6 (0.50)

patients with adenocarcinoma and large-cell carcinoma histology; in squamous cell histology, cisplatin and gemcitabine combination, was associated with improvement in survival [75]. Hence, in patients with non-squamous histology, pemetrexed and platinum-based combination is preferred.

8.3.1 Targeted Therapy

Recent advances in our understanding of the molecular biology of NSCLC, including both the genomic alterations that drive malignancy and the mechanisms of tumour immunologic escape, have led to new and exciting treatment approaches. The identification of tyrosine kinases oncogenic activation in NSCLC, such as epidermal growth factor receptor (EGFR) mutation or anaplastic lymphoma kinase (ALK) gene rearrangement has enabled novel targeted molecular treatments.

Small molecule tyrosine kinase inhibitors (TKIs) targeting mutant EGFR have been approved by the Food and Drug Administration (FDA) as first-line agents in the treatment of mutation positive advanced NSCLC patients. Gefitinib and erlotinib are reversible competitive inhibitors of ATP for the tyrosine kinase domain of EGFR resulting in blockade of downstream pathways; they were the first EGFR TKIs to be developed. Afatinib inhibits the entire ErbB/HER family of receptors. The landmark IPASS study randomised 1217 east Asian patients with untreated stage IIIB or IV adenocarcinoma to gefitinib or chemotherapy. Patients with sensitizing EGFR mutations who received gefitinib had increased PFS (24.9% vs. 6.7%), better response rates and improved quality of life [76]. Various trials comparing different TKIs to chemotherapy, specifically in EGFR-mutated NSCLC, have consistently demonstrated that first-line EGFR TKIs resulted in superior overall response rate (ORR), PFS and quality of life compared to systemic chemotherapy. However, at present there are no published head-to-head studies comparing the efficacy of various first-line EGFR TKIs [77].

In general, most of these agents demonstrate similar efficacy, hence the choice of agent depends on toxicity or clinician preference. A study (CALGB 30406) comparing erlotinib with or without chemotherapy showed that erlotinib alone was associated with similar efficacy and fewer side effects [78]. Most patients with sensitizing EGFR mutation develop resistance and progress after 10–13 months of TKIs. EGFR T790M is associated with acquired resistance to first-line TKIs and reported in 60% patients with progression after response to initial TKIs. Osimertinib is an oral TKI that inhibits both EGFR mutations and T790M has been recently approved as a first-line therapy based on the phase I (AURA) and phase III (FLAURA) studies [79, 80].

Crizotinib is a small molecule inhibitor of the ALK, MET and ROS tyrosine kinases. Based on the results from the single-arm, global Phase II PROFILE 1005 study, crizotinib received an accelerated approval from the US FDA in 2011, because of its efficacy in ALK positive NSCLC [81]. Subsequently phase III studies have shown higher response rates and PFS benefit for crizotinib as second-line therapy in ALK positive NSCLC [82]. The PROFILE 1014 trial showed a PFS improvement of crizotinib (10.9 months vs. 7 months) over standard chemotherapy in first-line setting and has cemented its status as the first-line option in ALK positive NSCLC [83].

As with EGFR TKIs, various mechanisms (including ALK amplification, EGFR/HER1, HER2 and HER3 up-regulation, cKIT amplification and ALK mutations including L1196M) can lead to development of resistance to crizotinib for ALK rearranged NSCLC. In ALK positive patients who progress on first-line crizotinib, subsequent therapy options include alectinib, ceritinib, or brigatinib. Two phase III studies have demonstrated superiority of alectinib as first line in ALK positive NSCLC [84, 85]. Ceritinib, a second-generation ALK inhibitor, is 20 times more potent ALK inhibitor than crizotinib.

As there is a 50% sequence homology between ROS1 and ALK, ALK inhibitors such as crizotinib and ceritinib can inhibit both kinases yielding response rates of approximately 70–80%.

8.3.2 Immunotherapy

Immunotherapy for advanced NSCLC has completely changed the treatment landscape and has resulted in a new paradigm of treatment options resulting in improved survival, better response rates and safer yet unique toxicity profile compared to conventional systemic chemotherapy. Immunotherapy uses highly selective humanized monoclonal antibodies against checkpoint signals such as programmed cell death receptor (PD-1) and programmed cell death ligand (PD-L1). Blockage of these receptors and signals reactivates the immune system to target the tumour. PD-1 inhibitors such as nivolumab and pembrolizumab, and PD-L1 inhibitor, atezolizumab, are currently approved by various regulatory authorities for the treatment of advanced NSCLC.

Nivolumab, a fully human IgG4 monoclonal antibody, selectively inhibits PD-1 activity by binding to the PD-1 receptor and blocks binding to its ligands PD-L1 and PD-L2. CheckMate 057 and CheckMate 017, two recently published phase III randomized studies demonstrated the clinical benefit with nivolumab as a second-line agent for advanced squamous and non-squamous NSCLC while reducing high-grade adverse effects. Compared to chemotherapy, nivolumab had a higher OS, PFS and response duration with any PD-L1 expression levels (>1%, 5% and 10%) [86]. Pembrolizumab, another PD-1 blocker is the first immune checkpoint blockade drug to be approved as first-line treatment for metastatic NSCLC with expression of PD-L1 on at least 50% based on the KEYNOTE 010 trial [87] and KEYNOTE 024 trial [88]. PD-L1 inhibitors inhibit the interaction between PD-1 and PD-L1, thus preventing the death of tumour-specific T-cells. Atezolizumab and durvalumab are the most common drugs in this class. Currently, many ongoing studies are investigating the combination of chemotherapy/radiotherapy and immune checkpoint inhibitors in patients with NSCLC. A comprehensive review is beyond the scope of this text and can be found elsewhere [89, 90].

9 Stage-Wise Management Algorithms

See Figs. 1, 2, 3 and 4.

Table 3 Common toxicities in treatment of NSCLC

Treament modality	Major toxicities
Surgery	**Intra-operative complications** Injury to major vessels Cardiac arrhythmia Myocardial ischaemia Contralateral pneumothorax Other complication (usually detected late) Injury to intrathoracic nerves, oesophagus, thoracic duct **Postoperative complications** Postoperative haemorrhage Cardiac arrhythmias Right to left shunting Pulmonary complications Air leak Chylothorax Lobar torsion
Radiation therapy	Pneumonitis (acute and chronic) Oesophagitis (acute) Cardiac toxicity (chronic) Brachial plexopathy (chronic)
Systemic therapy	**Cytotoxic chemotherapy** Hematological toxicity Non-hematological toxicity (Oto-, nephro-, neuro-, hepato-, cardiac and pulmonary toxicities) **Targeted agents** Skin and GI toxicity Pneumonitis Cardiac toxicity **Immunotherapy** Dermatological toxicity, Colitis Hepatotoxicity, pulmonary toxicity, Endocrinopathies

10 Toxicity of Treatment

A few of the common toxicities encountered with various treatment modalities in NSCLC are listed in Table 3**.**

11 Stage-Wise Prognosis with Current RX

The 5-year survival rate for different stages of NSCLC is as follows, for stage IA1, IA2 and IB 92%, 83%, and 68%, IIA and IIB is 60% and 53%, stage IIIA and IIIB is 36% and 26%, stage IV is less than 10%. Over the last decade, survival in lung cancer has increased from a median overall survival of 11 months to an overall 5-year survival rate of 17.8%. Identification of EGFR and ALK mutations in stage IV NSCLC has ushered in a new era in management and portends better prognosis, with observed median overall survival of more than 30 and 40 months, respectively.

12 How We Do It at TMC

See Table 4.

Table 4 How we do it at TMC

Surgery	
SBRT Dose: 60 Gy in 3–5# for peripheral tumours; 60Gy in 8# for central tumours using conformal radiotherapy techniques. BED more than 100Gy is recommended **Definitive RT—Conventional fractionation** Dose: 60–66 Gy/30–33#/6–7 weeks with 6 MV photons using conformal radiotherapy techniques **Adjuvant PORT** Dose: 50–54 Gy/25–27#/5–6 weeks with 6 MV photons using conformal radiotherapy techniques Lung dose: (volume both lungs and subtract PTV) for DVH calculation, to keep risk of grade 2+ radiation pneumonitis less than 20%. Aim: Mean lung dose <20 Gy,V20Gy < 30–35% (concurrent chemoradiotherapy / radiotherapy)	
Palliative radiotherapy doses for locally advanced /metastatic lung cancer **Thoracic palliative radiotherapy / superior vena cava syndrome:** 30–39 Gy/10–13#/2.5 weeks or 20 Gy/5# over 1 week 17 Gy/2 Fr/weekly once (for poor performance status patients) **Metastatic disease** Parenchymal brain metastases with good performance status: Whole brain radiotherapy: 30 Gy/10#/2 weeks followed by boost to gross lesion With poor performance status: Whole brain radiotherapy—20Gy/5#/1 week Spinal cord compression: 30 Gy/10#/2 weeks (or) 20Gy/5#/1 week (or) 16Gy/2#/1 week Painful bone metastases: 6–8 Gy/1#; 20Gy/5#/1 week in case of associated pathological Fracture or soft tissue mass Rarely, hemi-body irradiation may be used for disseminated bone metastases **Endobronchial radiotherapy** Salvage treatment for recurrent/residual endobronchial lesion 7.5 Gy per # for 2 sittings a week apart	
Systemic therapy—NSCLC metastatic	
Front line—No targetable mutation **Non-squamous**	Paclitaxel 200 mg/m^2 + carboplatin AUC 6 + Atezolizumab 1200 mg + Bevacizumab 15 mg/kg (regardless of PDL 1) q 21 days Pembrolizumab 200 mg agent if PD L1 > 50%q 21 days Pemetrexed 500 mg / m2 + carboplatin AUC -6 + Pembrolizumab 200 mg if PD L1 < 50% q 21 days Paclitaxel 200 mg/m^2 + carboplatin AUC 6+ bevacizumab 15 mg/kg Pemetrexed 500 mg/m^2 + carboplatin AUC—6 q 21 days
Front line—No targetable mutation **Squamous**	Nab pacliataxel 100 mg/m^2 + carboplatin AUC—6 + pembrolizumab 200 mg q 21 days Gemcitabine 1200 mg/m^2 + Carboplatin AUC—6 q 21 days
Targetable mutations	
EGFR mutations	1. Afatinib 2. Erlotinib 3. Gefitinib 4. Osimertinib(T790M positive) 5. Erlotinib + bevacizumab
ALK gene rearrangements	1. Crizotinib 2. Ceritinib 3. Alectinib
Ros mutation	1. Crizotinib 2. Ceritinib
High-level met amplifications	1. Crizotinib

1 Introduction

Lung cancer is primarily classified histologically into non-small cell and small cell lung cancer. Small cell lung cancer (SCLC) is a neuroendocrine tumor with a high malignant potential. It is a highly aggressive tumor with a rapid doubling time and high growth fraction. SCLC has a high propensity for nodal metastasis, and nearly two-thirds present with metastatic disease with visceral and skeletal metastases. SCLC is a very chemo- and radiosensitive tumor, and both treatments form the mainstay of treatment.

2 Incidence and Epidemiology

Lung cancer is one of the most common cancer worldwide and fourth most common in India. It is also a leading cause of cancer-related mortality in the world and ranked third most common cause in India [1]. It accounts for approximately 10% of overall cancer mortality in India. SCLC accounts for 10–15% of all lung cancer cases worldwide. Smoking is the commonest risk factor for SCLC contributing to 95% of cases worldwide, and it mirrors the incidence of smoking patterns. SCLC is more prevalent in males as compared to females owing to more smoking rates; however, this difference is now shrinking and prevalence rates are same [2].

SCLC can present with symptoms due to local extension, extrathoracic extension, constitutional or paraneoplastic disorders. SCLC usually presents as a central lung mass with involvement of hilum as compared to peripheral disease in non-small cell lung cancer. Local symptoms like cough, chest pain, hemoptysis, and dyspnea are the most common symptoms at presentation. SCLC can also present with dysphagia, hoarseness, and superior vena cava syndrome owing to the compression or invasion of the esophagus, recurrent laryngeal nerve, and great vessels, respectively. Superior vena cava syndrome is present in 10% of patients and present with puffiness of the face, engorged neck veins, and breathing difficulty. Patients often report anorexia, fatigue, and weight loss due to the systemic nature of the disease. The majority of SCLC patients have metastatic disease at diagnosis [2] and have associated symptoms. Bony involvement is usually osteolytic and presents with bone pain. It can also manifest with metastatic spinal cord compression. Hepatic involvement is generally asymptomatic with increase in bilirubin, transaminase, and alkaline phosphatase. Adrenal lesions are asymptomatic and detected on imaging. CNS involvement is symptomatic and presents with a headache, vomiting, seizure, and associated symptoms depending upon the location of the lesions.

SCLC is the commonest cause of paraneoplastic syndrome among solid tumors [3] and can present with symptoms related to hormone secretion or immune-mediated response. The most common paraneoplastic syndrome is syndrome of inappropriate antidiuretic hormone (SIADH), which can cause euvolemic hyponatremia, concentrated urine, and reduced plasma osmolality. Cushing disease (excess ACTH secretion), Lambert-Eaton syndrome, hypercalcemia, and hypertrophic pulmonary osteoarthropathy are the other common paraneoplastic disorders seen in SCLC.

3 Evaluation and Work-Up

Complete history and detailed physical examination of a patient suspected to have SCLC is of foremost importance as the patient can present with varied manifestation as described above. Chest X-ray is usually the first investigation and can demonstrate mediastinal widening, atelectasis, and pleural effusion. Blood investigations typically include complete blood counts (CBC), serum electrolytes, kidney and liver function tests, serum calcium, and lactate dehydrogenase. Imaging plays a very important role in the staging of SCLC. Contrast-enhanced computed tomography (CT) of the chest and upper abdomen can demonstrate the extent of the primary disease, mediastinal adenopathy, and adrenal gland involvement. Bone metastases can also be seen on the CT. F-18, fluorodeoxyglucose positron emission tomography (F^{18} FDG PET)/CT is performed to rule out the distant metastatic disease. If FDG PET is not available, then bone scintigraphy with technetium-99m methylene diphosphonate is recommended. FDG PET-CT can upstage the disease in approximately 15–20% of patients [4] and changes treatment decisions and radiotherapy target volumes [5]. Magnetic resonance imaging (MRI) of the brain is recommended for all patients, since brain metastases can present in 10–15% at diagnosis, including 10% of asymptomatic patients [6]. Incidence of brain metastases increases with the stage of the disease. Most common sites of metastatic disease are bone, liver, brain and adrenal glands.

4 Pathology

The diagnosis of SCLC can be established by fluid cytology, percutaneous transthoracic biopsy or bronchoscopic biopsy. On H& E stain, SCLC is a small blue round cell tumor with scant cytoplasm, finely granular nuclear chromatin, absent or inconspicuous nucleoli with ill-defined borders [3, 7]. SCLC has a high mitotic rate, and extensive necrosis is typically present. Crush artifact is more commonly encountered in SCLC in biopsy specimens. In resected specimens, small cell is usually larger than seen in biopsy specimens because of better fixation. SCLC is usually described as pure SCLC or combined SCLC. Combined SCLC is usually present in combination with another non-small cell histologies adenocarcinoma, squamous and large cell carcinoma. In difficult diagnosis, immunohistochemistry markers can be useful like pan-cytokeratin antibody (AE1/AE3), neuroendocrine markers (chromogranin, synaptophysin, CD56), thyroid transcription factor (TTF-1), and ki-67. TTF-1 is positive in approximately 75–80% of cases [8, 9]. Ki-67 is a proliferative marker and ranges up to 60–80% in SCLC and can be used to differentiate other neuroendocrine tumors from SCLC.

5 Staging

Historically, SCLC for all practical purpose was stage into limited stage (LS) and extensive stage (ES) in 1950s by the Veterans' Administration Lung Study Group (VALSG) depending on whether the disease can be encompassed in a single and safe radiation portal [10, 11]. Limited stage was defined as disease confined to one hemithorax, local extension, and ipsilateral supraclavicular node included if they can be encompassed in safe radiation portal. All other disease that cannot be encompassed in a radiation portal including extrathoracic metastases were defined as extensive stage. In 1989, the International Association for the Study of Lung Cancer (IASLC) modified limited stage definition as disease confined to one hemithorax with regional lymph node metastases including hilar, ipsilateral, or contralateral mediastinal/supraclavicular nodes. They also included ipsilateral pleural effusion irrespective of cytology in limited stage. This staging system was used in clinical practice for almost six decades. As majority present in advance or metastatic stage surgery has no role, hence, TNM staging was very infrequently used in clinical practice. However, it was applicable for SCLC and few surgical series showed TNM to be of prognostic significance. In year 2007 with proposed changes for seventh edition of TNM, IASLC recommended that AJCC TNM should be used for staging of SCLC [12]. For TNM staging and grouping, kindly refer to the chapter of NSCLC. Though prognostically validated, this staging system is too cumbersome, and management remains same for most of the stages in routine clinical practice. Disease more extensive than described above is considered extensive stage (ES) disease. Accurate staging of SCLC is essential since treatment decision changes accordingly.

6 Principles of Management

As SCLC is a very aggressive malignancy, the principle is to start treatment as early as possible after confirmation of diagnosis and discussion in multidisciplinary tumor board.

Table 1 Management of SCLC

6.11.Stage	Standard management	Radiation	Chemotherapy	5-year OS
Limited stage (T1, T2), N0, M0	Mediastinal lymph node dissection and lobectomy	If node positive	Adjuvant chemotherapy cisplatin + etoposide	40–45%
Limited stage (T1-T4, N1-N3, M0)	Concurrent CTRT	Conformal RT (dose—45 Gy/30 Fr, 1.5 Gy bid) or 60 Gy in 30 Fr	Cisplatin + etoposide (3 weekly)	20–25%
Extensive stage (any T, any N, M1)	Palliative chemotherapy	Any response—PCI (dose-25 Gy/10 Fr) ± consolidative RT to the chest	4–6 cycles of carboplatin + etoposide (3 weekly)	0–5%

OS overall survival, *CTRT* chemoradiation, *RT* radiotherapy, *PCI* prophylactic cranial irradiation, *T* tumor, *N* node, *M* metastases

Overall management of SCLC is outlined in Table 1. Majority presents with metastases (extensive stage) hence, chemotherapy is the mainstay of treatment of SCLC. Symptomatic treatment and supportive care are also indicated apart from chemotherapy. In LS-SCLC, a combination of chemotherapy and radiation therapy is the standard of care. Prophylactic cranial irradiation is recommended after completion of therapy in LS and ES-SCLC to reduce the incidence of brain metastases. Surgery is done in less than 5% of LS-SCLC. Overall, SCLC has a dismal survival rate with a median OS of 3–4 months in the absence of treatment. According to SEER database, 5-year OS for limited stage is 20–25% and < 5% for extensive stage disease. TNM staging better prognosticates patients of SCLC and 5-year OS of stage I, II, III, and IV is reported as 38%, 18%, 11%, and 1%, respectively.

7 Limited Stage SCLC

7.1 Surgical Management

Surgery has a very limited role to play in the management of localized SCLC. In very early stage with no documented mediastinal nodes on PET-CT and EBUS (T1/T2 N0 M0), surgical resection consists of mediastinal lymph node dissection with lobectomy [13]. The incidence of lymph node metastases is still considerably high and hence adjuvant chemotherapy is recommended for all patients after resection. The adjuvant chemotherapy consists of four cycles of cisplatin-based regimens [14]. Pathological node-positive patients will require adjuvant concurrent chemoradiation therapy [15]. In ES-SCLC, surgery has no role except palliative fixation of pathological fractures.

7.2 Radiation Management

In very early-stage SCLC (T1/T2N0M0) patients, those who are not suitable or refused surgery, stereotactic body radiation therapy could play a role. However, there is very limited data available as patient population in this cohort is extremely small. A recent systematic review concluded that SBRT in stage I SCLC could be a potential option with comparable outcomes and no added toxicities [16]. In majority of LS-SCLC, definitive radiation therapy concomitant with Cisplatin-Etoposide chemotherapy is the standard of care. Two meta-analysis including Pignon et al. of 13 randomized controlled trials (RCTs) showed that thoracic radiotherapy improved overall survival (OS) by 5.4% at 3-year vs. chemotherapy alone [17, 18]. As lung tumor moves with respiration, radiation planning with adequate immobilization and motion management strategies like four-dimensional computed tomography (4DCT), gating and tracking should be utilized according to the institutional protocol. At TMH, 4DCT radiation planning with target delineation on maximum intensity projection (MIP) datasets and treatment planning on free breathing scan is done. Three-dimensional conformal radiation therapy (3D-CRT)/intensity-modulated radiation therapy (IMRT) are the preferred radiation planning techniques.

7.2.1 Timing of Thoracic RT

Timing of thoracic RT with chemotherapy has always remain a topic of debate and controversy. Various phase III studies have evaluated the timing of thoracic RT with chemotherapy and showed mixed results for survival outcomes. Three RCT showed significant benefit in terms of OS for early thoracic RT compared with delayed thoracic RT [19–21]. Several systematic review and meta-analysis also reported that early concurrent thoracic RT is beneficial as compared to delayed RT [22–24]. Individual patient data meta-analysis also supports early and shorter thoracic RT for overall survival benefit as compared to delayed and longer RT [25]. Also, overall treatment duration from the start of chemotherapy to last day of radiation also predicted outcome in one of the systematic reviews [23]. NCCN guidelines also recommend that concurrent thoracic RT should commence from cycle one or two of chemotherapy.

7.2.2 Dose of Thoracic RT

Various total doses and fractionation schedules of radiation therapy are supported in literature (Table 2), and different institutes use dose schedules according to their institutional

Table 2 Studies evaluating accelerated regimens of RT in LS- SCLC

Study	RT	CT	OS	PFS	Esophagitis (%)
INT 0096 (1999)	B.I.D (45 Gy/30 Fr) OD (60 Gy/30 Fr)	EP	26% (5 years) 16% (5 years)	29% (2 years) 24% (2 years)	27 11
Schild et al (2004)	BID—48 Gy/32 Fr OD—50.4 Gy/28 Fr	NACT −3 #EP ➔ CTRT	21% (5 years) 22% (5 years)	21% (5 years) 19.8% (5 years)	05 12
RTOG 0239 (2012)	61.2 Gy/ 34 Fr [1.8 Gy OD (d1–d22) ➔1.8 Gy B.I.D (d22–d33)]	EP	36.6% (2 years)	19.7% (2 years)	18
CONVERT (2017)	BID—45 Gy/30 Fr OD—66 Gy/33 Fr	EP	56% (2 years) 51% (2 years)	15.4 months 14.3 months (median)	19 19

OD once daily, *BID* twice daily, *Fr* fraction, *RT* radiotherapy, *CT* chemotherapy, *EP* etoposide cisplatin, *PFS* progression-free survival, *OS* overall survival

practice. Radiation doses schedule ranges from accelerated regimen of 45 Gy/30 fraction at 1.5 Gy/fraction twice daily, 6 h apart over a period of 3 weeks [26] to hypofractionated regimen of 40 Gy/15 fractions over 3 weeks [27] or conventional regimen of 60 to 66 Gy/30–33 fraction once daily at 2Gy per fraction over a period of 6 weeks. Accelerated fractionation regimens are used to counter rapid proliferation of small cell tumors. EORTC study published in 1999 showed accelerated twice-daily radiation (45 Gy/30 Fr) resulted in improvement of 5-year OS of 26% vs. 16% for once daily (45 Gy/30Fr) ($P < 0.04$). The incidence of grade III esophagitis (27%) was higher in twice-daily arm. Criticism of this trial was the lower biological dose in once-daily arm compared to twice-daily arm. Phase II study by RTOG 0239 evaluated accelerated regimens of 61.2 Gy over 33 days along with cisplatin and etoposide and demonstrated inferior 2-year OS of 37% and lower grade III esophagitis of 18% compared to INT 0096 [28]. Contrary to INT 0096 study, recently published superiority trial of once daily over twice daily (CONVERT) showed no significant difference between once-daily and twice-daily regimens and concluded that twice-daily regimens should continue to be the standard dose regimens. However, in resource-constrained countries like India, once-daily regimen of 60 Gy/30 fractions is most commonly used regimen because of logistical reasons.

7.2.3 Role of PCI

After completion of planned treatment, prophylactic cranial irradiation (PCI) is recommended at a dose of 25 Gy/10 fractions since the brain is the common site of relapse. Two-year cumulative risk of developing brain metastases is approximately 50% [29]. Meta-analysis of 7 randomized trials by Auperin et al. has shown a reduction in the risk of brain metastases by 50% and improvement in overall survival by 5.4% at 3 years with PCI compared with no PCI [30]. A second meta-analysis also confirmed the beneficial effects of PCI [31]. However, the role of PCI is questioned in elderly, larger size tumors and patients with poor mentation [32]. Different dose fractionation schedules are used for PCI but most commonly used is 25 Gy/10 fraction. An RCT comparing 25 Gy versus higher dose of 36 Gy showed no difference in the incidence of brain metastases but worsened overall survival with higher dose [33]. PCI has more beneficial effect if started early after the completion of concomitant chemoradiation than delayed after the completion of chemotherapy cycles [34, 35]. Prospective literature is limited except one small RCT which shows no significant benefit of early PCI within 60 days of induction treatment although timing of chemotherapy was confounding factor [36]. PCI if delayed, then higher doses of PCI are required for reducing the incidence of brain metastases [37]. PCI has been shown to cause neurocognitive deficits (NCD) in various studies [37, 38]. Various other factors affect neurocognitive decline like total dose and fractionation, age, type, and timing of chemotherapy [39, 40]. Pre- and post-PCI neurocognitive assessment were done in a single study and showed that approximately 50% of patients had pre-existing neurocognitive deficits. Also, NCD was not sustained and showed continuous improvement with time [41]. Memantine and hippocampal avoidance are the strategies used to treat and prevent neurocognition decline with PCI [42, 43].

7.3 Chemotherapy

Chemotherapy is the main form of treatment in the management of SCLC because of its disseminated nature. In limited stage, cisplatin and etoposide (EP) regimen is the standard of choice based on the results of studies partly from both, limited and extensive SCLC (Table 3). Cisplatin is given at a dose of 80 mg/m^2 IV on day 1 and etoposide 100 mg/m^2 IV on day 1–3 every three week. Initially, Cyclophosphamide, Adriamycin and Vincristine (CAV) based regimen was used for the treatment of SCLC with good response rates. In a randomized comparison of CAV, EP or alternating regimens in 288 patients by Fukuoka et al., they showed significantly

Table 3 Chemotherapy trials in LS and ES-SCLC

Study	Arms	OS (months)		PFS/HR of survival distribution		Toxicity	
Fukoka et al	CAV	12.4	$p = 0.80$	–		Leucopenia ($p < 0.001$)	78%
	EP	11.7		–			46%
	CAV /EP	16.8		–			72%
ELCWP (meta-analysis)	I-CDDP vs. non CDDP or VP-16	–		0.70		–	
	II-VP-16 vs. non CDDP or VP-16	–		0.72		–	
	III- CDDP + VP-16 vs. non CDDP or VP-16	–		0.57		–	
	IV—CDDP + VP-16 vs. VP-16	–		0.74		–	
COCIS meta-analysis	CDDP based	9.6	HR 1.08	5.5	HR1.1	Neutropenia	86 vs. 90(0.357)
	Carboplatin based	9.4		5.3		Low platelets	39 vs. 71(0.001)
						CINV	72 vs. 63(0.12)
						Nephrotoxicity	25 vs. 10 (0.001)
ES-SCLC							
IMpower 133	VP-16+ carboplatin + Atezolizumab vs. VP-16 carboplatin + placebo	12.3 vs. 10.3 (HR-0.70)		5.2 vs. 4.3 (HR-0.77)			

CDDP cisplatin, *VP-16* toposide, *CAV* cyclophosphamide + Adriamycin + vincristine, *EP* etoposide platinum, *IP* irinotecan platinum, *CINV* chemo-induced nausea and vomiting, *PFS* progression-free survival, *OS* overall survival, *HR* hazards ratio

better response rates with EP and alternating regimens as compared to CAV regimen [44]. Two systematic review and meta-analysis also showed superiority of cisplatin and etoposide-based regimens in terms of response rates and overall survival as compared to other alkylating agents [45, 46]. However, cisplatin has higher non-hematologic toxicity rates in the form of nephrotoxicity, ototoxicity, and neurotoxicity and hence cisplatin substitutes with better toxicity profile-like carboplatin have been tested in various RCTs in initial management of SCLC. Meta-analysis with individual patient data demonstrated equivalent OS, PFS, and ORR; however, hematologic toxicity were significantly less for cisplatin-based regimens [47]. Thus, cisplatin or carboplatin plus etoposide is widely used initial regimen for LS-SCLC along with early thoracic RT.

8 Extensive Stage SCLC

Majority of patients present in extensive stage disease and have distant metastases, pleural or pericardial effusion or para neoplastic syndromes. Initial management depends upon initial presentation and directed at symptomatic relief and early initiation of systemic therapy. Patients presenting with superior vena cava syndrome can be managed with endovascular stenting which gives good immediate symptomatic relief with minimal toxicity. Chemotherapy also gives fast symptomatic relief in approximately 80% patients as SCLC is a very chemo-sensitive tumor. Radiation therapy is also recommended as initial treatment or as adjuvant to stenting. Effect usually takes 48 to 72 h and majority will give symptomatic relief within 1 week. Tumor lysis syndrome should be managed with adequate hydration, appropriate electrolyte correction, and xanthine oxidase inhibitor therapy.

8.1 Chemotherapy

Platinum-etoposide doublet chemotherapy for 4–6 cycles is the initial recommended treatment for extensive stage SCLC. As stated above in LS-SCLC, two meta-analyses have shown superiority of EP regimen over other alkylating regimens. Various RCT also evaluated irinotecan platinum versus EP regimen in untreated ES-SCLC with contradictory results. Meta-analysis by Jiang et al. showed similar PFS and suggested possible benefit in OS with different toxicity profile. Irinotecan regimens produced less hematological toxicity but higher grade 3 or 4 vomiting and diarrhea. They concluded that irinotecan-based regimen is a good alternative to EP regimen in ES-SCLC [48]. Various other chemotherapeutic agents like epirubicin, topotecan, taxanes were combined with cisplatin on the basis of phase II studies to improve the response rates; however, they failed to show any significant benefit. Other strategies like alternating non-cross resistant regimens, multiple drug combinations, and dose intensification also failed to show any benefit over EP regimen. Therefore, cisplatin and etoposide regimen remains the standard of choice for initial management of extensive stage SCLC.

8.2 Duration of Treatment

Four to 6 cycles of EP regimen is the acceptable standard duration; however, it is not well defined in literature.

8.3 Targeted/Immunotherapy

Bevacizumab-based maintenance regimens after completion of planned PE regimens have also been tested in a phase III trial and concluded no significant benefit in OS. Recently, immune checkpoint inhibitors have gained importance since its success in NSCLC and have also been tested in SCLC. In a recently published RCT, carboplatin and etoposide were given concurrently with either atezolizumab, a PD-L1 inhibitor, or placebo for 4 cycles and then as maintenance atezolizumab versus placebo till disease progression. It showed a significant increase in median OS (HR −0.70) and PFS (HR −0.77) with comparable toxicity profile [49].

8.4 Radiation Therapy

After completion of planned chemotherapy, if there is no progressive disease, PCI is recommended to reduce the incidence of brain metastases in future. EORTC published a randomized study in 2007 which showed a statistically significant reduction in the risk of brain metastases, improvement in disease-free survival, and overall survival with PCI compared to no PCI [50]. The cumulative risk of symptomatic brain metastases at 1 year reduced from 40.4% to 14.6% with PCI. Criticism of this study was that brain imaging was not done before randomization to rule out brain metastases. As PCI has neurocognitive side effects, many studies have questioned the benefits of PCI especially in elderly or patients with poor mentation status at baseline as the prognosis of ES-SCLC is extremely poor. Recently published multicentric RCT of PCI vs. no PCI from Japan [51] acquired MRI brain at baseline and at follow-up assessment. The results showed that PCI did not improve OS and DFS but reduced the risk of brain metastases. Cumulative incidence of brain metastases at 18 months in the PCI group was 40.1% as compared to 63.8% in the observation group. Hence, PCI in ES-SCLC remains controversial until this date.

Consolidative RT to the chest after completion of planned chemotherapy in ES-SCLC is also a topic of debate. Jeremic et al. in 1999 published a RCT of a subset of patients with good response with CR at distant level and at least PR at primary level between accelerated hyper fractionated RT (54Gy in 36 fractions twice daily over 18 days) with chemotherapy compared with additional CT only and demonstrated a good OS rate in favor of consolidative RT to chest [52]. Slotman et al. in 2015 published another RCT in patients with any response to CT between consolidative RT to the chest (30 Gy in 10 fractions daily) compared with observation. The primary endpoint of 1-year OS did not show any benefit of RT (33% vs. 28%, $p = 0.066$); however, 2 years OS was significantly better (13% vs. 03%, $p = 0.004$) with reduced intrathoracic progression [53]. Secondary analysis showed patients benefitted from RT if any residual disease [54] or fewer than two sites of extrathoracic metastases [55]. Meta-analysis of three RCT showed improvement in progression-free survival with HR of 0.72 with reduction in intrathoracic failure, but no benefit in OS with HR of 0.88 [56]. Aggressive RT to the chest and less than four extrathoracic metastases was also studied in a phase II RCT in comparison to PCI alone and showed no difference in OS rate at 1 year but, as expected, resulted in lower rates of progression [57].

Palliative radiation therapy to symptomatic sites such as bone or brain is often warranted during the initial management of ES-SCLC. Doses ranging from 8 Gy in single fraction to 20–30 Gy in multiple fractions predominantly depend upon performance status, site of metastases, and bulk of the disease. Palliative RT gives good symptomatic relief in bony pain, cord compression, and brain metastases related symptoms.

9 Relapsed SCLC

SCLC usually relapse in majority of patients within initial 10–12 months in limited stage and 4–6 months in extensive stage. Treatment of relapse SCLC depends on patient performance status, time to relapse, and response to initial therapy. Broadly, if relapse occurs within first 6 months, initial platinum-based chemotherapy can be repeated. Various second-line single agents or two drug combination have been tested at relapse with very little success. Single agent's chemotherapeutic drugs like topotecan, irinotecan, taxanes, gemcitabine, vinorelbine, etc. have showed success in controlling the disease. In a multicenter randomized study, topotecan was compared with CAV regimen and showed comparable response rates with very good symptom control rates. Immune checkpoint inhibitors like nivolumab and ipilimumab have been tested in various phase II studies recently; however, no phase III study data is available till date. FDA has approved nivolumab as third-line treatment option.

10 Future Perspective

Immune checkpoint inhibitors alone or in combination with standard chemotherapy are being studied in various phase II studies. Hopefully, it would change the management of SCLC and improve treatment outcomes.

Table 4 Management of SCLC at TMH

Stage	Radiation	Chemotherapy	Surgery
Limited stage	60 Gy in 30 Fr OD with 3D-CRT/IMRT technique (usually with second cycle of CT)	Cisplatin (80 mg/m^2, D1) and etoposide (100 mg/m^2, D1-D3) every 3 weeks for 4–6 cycles f/b active surveillance	Lobectomy and mediastinal LN dissection (very rarely done)
Extensive stage	PCI—24.75 Gy/11 Fr if any response after chemotherapy	Carboplatin –AUC 5-6 (preferred) + Etoposide (100 mg/m^2, D1-D3) + Atezolizumab 1200 mg/m^2 every 3 weeks for 4-6 cycles f/b Atezolizumab maintenance till progression/toxicity. Alternative—Cisplatin 75 mg/m^2 d1 or 25 mg/m^2 d1-d3 and etoposide (as above) 3 weekly for 4–6 cycles. In relapse <6 months—Topotecan 1.5 mg/m^2 IV daily over 30 min. Repeat cycle every 3 weeks. Days 1–5	Palliative fixation of pathological fractures
	SVC syndrome Good GC—20 Gy/5 Fr Poor GC—17Gy/2 Fr		
	Bone metastases 8 Gy/single fraction 20 Gy/5 Fr (soft tissue)		
	Brain metastases 20 Gy/5 Fr (most common)		

OD once daily, *Fr* fraction, *3D CRT* three-dimensional conformal radiotherapy, *IMRT* intensity-modulated radiotherapy, *AUC* area under curve, *SVC* superior vena cava, *GC* general condition

11 How We Do It at TMC (Table 4)

All patients get the initial work-up done, including CT-guided biopsy, PET-CT, and MRI brain at baseline. Appropriate investigations required for fitness of chemotherapy and radiation therapy (pulmonary function test) are usually performed. All limited stage disease (TNM stage I, II, and III) are treated with concurrent chemoradiation therapy with cisplatin and etoposide as preferred chemotherapeutic agents on 3 weekly regimens. Radiation therapy planning is done with motion encompassing techniques—4D CT to account for tumor motion. All patients are planned with conformal techniques (3D CRT/IMRT/VMAT) with image guidance to a dose of 60 Gy/30 fractions treated once daily. PCI is recommended in all patients with parallel opposed techniques to a dose of 25 Gy/10 fractions. In less than 5% of patients, surgery is recommended for node-negative early-stage SCLC patients with lobectomy and mediastinal lymph node dissection after ruling out mediastinal node involvement with EBUS and PET-CT. First follow-up is usually done at 8 to 10 weeks, and blood investigations and PET-CT are done for response assessment. Thereafter, 3-month follow-up with CT thorax done every 6 months for 2 years and then 6 monthly follow-up until 5 years.

In ES-SCLC, platinum-based palliative chemotherapy for 4–6 cycles is the recommended treatment. Response assessment is done after every 3 cycles. Appropriate palliative radiation therapy to symptomatic sites if required and early palliative care referrals are usually sought. After completion of planned chemotherapy, response assessment is done with CT imaging and if partial or complete response, PCI is usually offered.

Abbreviations

AFP	Alpha-fetoprotein
anti-AchR	Anti-acetylcholine receptor
beta-HCG	Beta-human chorionic gonadotropin
DW MRI	Diffusion-weighted MRI
GCT	Germ cell tumors
IMRT	Intensity-modulated radiotherapy
ITMIG	International Thymic Malignancy Interest Group
IV	Intravenous
LDH	Lactate dehydrogenase
MG	Myasthenia gravis
MRI	Magnetic resonance imaging
NSGCT	Nonseminomatous germ cell tumors
PRCA	Pure red cell aplasia
TK	Tyrosine kinase
VATS	Video-assisted thoracoscopic surgery
WHO	World Health Organization

1 Introduction

Mediastinal tumors include a heterogeneous group of neoplasms, both benign and malignant arising from the mediastinum. The mediastinum is defined as a closed cavity starting superiorly from the thoracic inlet to the diaphragm inferiorly, bounded on either sides by lung hila, anteriorly by the sternum and posteriorly by the vertebrae. It is further divided into three or four compartments to help categorize tumors according to their site of origin and location. The three-compartment model describes anterior, middle and posterior divisions, while the four-compartment model has an additional superior mediastinal compartment [1]. The anterior compartment extends from the posterior surface of the sternum to the anterior aspect of the great vessels and pericardium. The thymus, lymph nodes, internal mammary arteries, connective tissue and fat are the major components. The middle compartment contains the pericardium, heart, great vessels, airway and esophagus and is bounded by the pericardium anteriorly and the ventral surface of the thoracic spine posteriorly. The posterior compartment includes the spine and the costovertebral sulci. It contains the neurovascular bundles, spinal ganglia, sympathetic chain, lymphatic tissue, descending thoracic aorta, esophagus, azygos veins and fat.

2 Incidence and Epidemiology

Thymomas, neurogenic tumors and benign cysts account for approximately 60% of mediastinal masses while lymphoma, teratomas and granulomatous diseases contribute to the rest. The majority (50%) of mediastinal tumors arise in the anterior mediastinum including thymoma, teratoma, lymphoma and thyroid disease (Table 1) [2]. Masses of the middle mediastinum are usually congenital in origin and cystic,

Table 1 Anatomical location of mediastinal mass

Anterior mediastinum	Middle mediastinum	Posterior mediastinum
Thymoma	Lymphoma	Neurogenic tumors
Teratoma, seminoma	Pericardial cyst	Bronchogenic cyst
Lymphoma	Bronchogenic cyst	Paravertebral abscess
Intrathoracic goiter		Meningocele
Carcinoma		Diaphragmatic hernia
Lipoma		
Parathyroid adenoma

while those arising in the posterior mediastinum are most often neurogenic tumors [3]. While exact figures regarding incidence are unknown for this heterogeneous group, the incidence of thymic neoplasms is around 1.5 per million person-years as per the SEER database.

3 Clinical Presentation

The clinical presentation of mediastinal neoplasms is variable. Most often, patients present with an incidental finding on imaging during routine clinical examination. Such incidentally discovered masses generally tend to be benign. Malignant masses are more likely to be symptomatic. Symptoms may be due to compression or infiltration of surrounding vital structures or systemic due to paraneoplastic syndromes. Cough (60%), chest pain, fever and dyspnea are the most common symptoms at presentation. Some tumors may present with more life-threatening symptoms like superior vena cava obstruction, stridor due to tracheal compression or hypotension due to cardiac or pulmonary artery compression. Involvement of nerves is a common finding, particularly in malignant tumors, with the recurrent laryngeal nerve, phrenic and the posterior nerve roots being most commonly affected. Systemic symptoms are typically due to the secretion of excess hormones, antibodies or cytokines. A variety of paraneoplastic syndromes are known to be associated with mediastinal masses (Table 2).

Table 2 Paraneoplastic syndromes associated with mediastinal masses

Syndrome	Tumor
Myasthenia gravis RBC aplasia Hypogammaglobulinemia Good syndrome Whipple's disease Megaesophagus Myocarditis	Thymoma
Multiple endocrine adenomatosis Cushing's syndrome	Carcinoid Thymoma
Hypertension	Pheochromocytoma Chemodectoma Ganglioneuroma
Diarrhea	Ganglioneuroma
Hypercalcemia	Parathyroid adenoma Lymphoma
Hypoglycemia	Mesothelioma Teratoma Fibrosarcoma Neurosarcoma
Osteoarthropathy	Neurofibroma Mesothelioma
Vertebral anomalies	Enteric cysts
Opsomyoclonus	Neuroblastoma

4 Evaluation and Work-Up

A thorough history and physical examination is critical in the initial evaluation of mediastinal masses, supplemented by laboratory and imaging studies. It is not uncommon to find testicular masses on imaging while investigating mediastinal masses. A careful history regarding any testicular swelling, undescended testes or previous scrotal surgery should be elicited, particularly in young males. History regarding early myasthenic symptoms like ptosis or dysphagia should also be elicited. Physical examination should include scrotal examination, abdominal examination for retroperitoneal masses and supraclavicular fossa examination.

4.1 Tumor Markers

Alpha-fetoprotein (AFP) and beta human chorionic gonadotropin (beta-HCG) are frequently elevated in germ cell tumors. AFP is elevated in 60% to 80% of nonseminomatous germ cell tumors (NSGCT) and beta-HCG is raised in 10% of seminomas and 30% to 50% of NSGCT [4]. While the absence of elevated tumor markers does not preclude the diagnosis of germ cell tumors, grossly elevated tumor markers clinch the diagnosis and may obviate the need for biopsy confirmation. Lactate dehydrogenase (LDH) is a marker of cellular proliferation and is elevated in tumors with brisk mitoses, particularly so in lymphomas [5]; however, it is not very specific.

4.2 Radiology

Large mediastinal masses can be identified on chest radiography as a soft tissue opacity with loss of borders of normal mediastinal structures (silhouette sign). However, once an abnormality is identified on X-ray, cross-sectional imaging is mandatory to further characterize the lesion and guide further management. Computed tomography with intravenous (IV) contrast is the imaging modality of choice. It provides detailed information regarding the location, size, relationship to other structures and tissue characteristics, like presence of fat, fluid or calcifications (e.g., teratoma) (Fig. 1). Very often in mediastinal masses, characteristic imaging features help identify the primary pathology and guide further management without the need for an invasive biopsy.

Magnetic resonance imaging (MRI), although not routinely performed, may be useful in certain specific scenarios. It is superior to CT in distinguishing cystic from solid masses and infiltration of vascular structures [2]. MRI

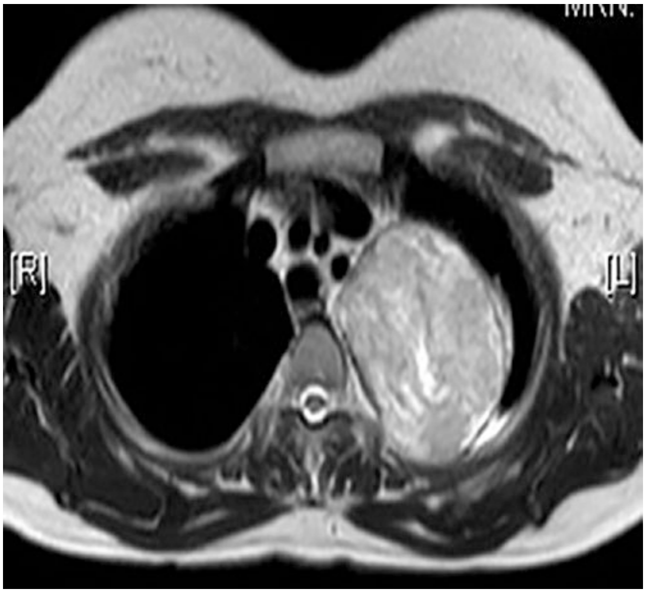

Fig. 2 MRI of posterior mediastinal neurogenic tumor

chemical shift imaging can be used to differentiate thymic hyperplasia from thymoma in adult patients [6]. MRI of the dorsal spine is occasionally warranted to evaluate extension of posterior spinal masses into neural foramina or spinal canal (Fig. 2).

18-FDG PET-CECT is mandated in the staging and monitoring of treatment response in lymphoma and is also occasionally used in the post chemotherapy response evaluation of seminomatous germ cell tumors. Recent reports suggest that it may also be useful in the evaluation of thymic neoplasms, actually predicting the WHO type accurately in 85% [7]. However, it is important to bear in mind that FDG-PET can be misleading, given that the normal thymus, hyperplastic thymus and inflammatory lesions in the mediastinum are all often FDG-avid [8].

4.3 Pathology/Tissue Diagnosis

Not all lesions in the mediastinum warrant a biopsy. Mediastinal masses with characteristic clinical symptoms like myasthenia gravis, pure red cell aplasia or hypogammaglobulinemia and characteristic radiological findings do not require biopsy confirmation before definitive treatment. The decision to biopsy or not becomes difficult when there is a clearly resectable anterior mediastinal mass but the clinical scenario does not allow definitive distinction between a lymphoma or thymoma. Tissue diagnosis is essential to characterize lymphomas and to avoid unnecessary surgery. On the other hand, a biopsy from an encapsulated thymoma carries the risk of tumor seeding along the needle tract and into the pleural cavity [9]. An extrapleural route with a coaxial needle system is the preferred approach to avoid seeding and dissemination of tumor into the pleural cavity. Biopsy techniques include CT-guided transthoracic needle biopsy [10], video-assisted thoracoscopic surgery (VATS), mediastinotomy and open surgical biopsy, with transpleural approaches being the least preferred. In case of posterior mediastinal masses, most are of neurogenic origin and can be characterized by MRI, biopsy being required rarely.

However, the dictum remains, “when in doubt confirm the diagnosis with a biopsy.” Histopathological confirmation is warranted in cases where diagnosis cannot be confirmed by tumor markers or radiology, surgery is not the primary modality of management, the lesion is unresectable or when systemic therapy is required.

5 Management

5.1 Thymoma

Thymic neoplasms are the most common tumors of the anterior mediastinum. They arise from the thymus, a lymphoepithelial organ, the functioning of which is vaguely understood. The thymus is known to play a role in T lymphocyte maturation in early age. Maximum size is achieved at the end of puberty and thereafter, it slowly involutes [11]. Histologically, it is divided into the outer cortex and inner medulla and is mainly composed of thymocytes, lymphocytes and epithelial stroma. Epithelial cells are further subtyped into six.

Thymomas are predominantly seen in middle and old age. In contrast to its developmental pattern, as the gland involutes, the incidence of malignancy increases [12]. The overall incidence of thymoma is 1.5 per million person years, as per the SEER (Surveillance, Epidemiology and End result) database [13]. Over 90% of thymomas are found in the anterosuperior mediastinum. They may also occur in ectopic thymic tissue, most commonly the lower neck, retrocarinal or aortopulmonary window region [14].

5.1.1 Classification
